Previously, drug absorption from the gut was assumed to occur by passive processes, and little attention was paid to the activity of counter transport systems. It has now been recognized that P-glycoprotein (P-gp), an ATP-dependent efflux transporter, is expressed at high levels on the apical surface of the columnar epithelial cells in the jejunum of the small intestine (21). P-gp represents the best studied member of the ATP binding cassette (ABC) family of transporters, and is the product of the multidrug resistance gene MDR1 in man. P-gp is expressed in a wide variety of tissues including the adrenal glands, the bladder, the cells of the blood–brain barrier, kidney, liver, lungs, pancreas, rectum, spleen, and most importantly for the purpose of oral bioavailability, in the esophagus, stomach, jejunum, and colon (21–23). In an apparent contrast to the situation noted above for CYP3A, levels of P-gp increase longitudinally along the intestine, with the lowest levels found in the stomach and the highest levels found in the colon (23).

The co-importance of CYP3A and P-gp for the oral bioavailability of drugs is suggested by their shared locations within the enterocytes of the small bowel, as well as a significant overlap in their substrate specificities (21, 24–28). Intracellularly, P-gp is found traversing the plasma membrane of enterocytes while CYP3A is found within the cytoplasm on the endoplasmic reticulum. Although gene expression of these two proteins does not appear to be coordinately regulated (29, 30), their proximal spatial relationship suggests that P-gp may act to regulate exposure of drug (substrates) to metabolism by CYP3A. Repeated absorption and extrusion processes would then, result in repeated exposure of drug to CYP3A, resulting in enhanced overall metabolism, and correspondingly lower oral bioavailability, as depicted in Fig. 4. This spatial juxtaposition, coupled with the large number of overlaps between CYP3A and P-gp substrates, suggests a strong

Fig. 4 This cartoon depicts the various processes leading to an oral bioavailability of 27%, following an oral dose of the Sandimmune® formulation of cyclosporine (15). The values at the bottom of the figure indicate the average fraction of the dose lost in each of the processes; i.e., 14% of the dose is either unabsorbed, counter transported (effluxed) by P-gp, or degraded in the gut lumen, 51% of the drug is metabolized in the enterocytes of the gut wall, and only 8% is lost due to hepatic first-pass metabolism.

complementary role for these proteins in the pharmacokinetics of drug absorption.

Oral bioavailability (F_{oral}) is equal to the product of the fraction of dose absorbed (F_{abs}), the fraction of the absorbed dose which passes into the hepatic portal blood flow unmetabolized (F_G), and the hepatic first-pass availability (F_H), as seen in Eq. 18.

$$F_{\text{oral}} = F_{\text{abs}} F_G F_H \quad (18)$$

Gut and hepatic availability may be defined as one minus the extraction ratio (ER) at each site.

$$F_{\text{oral}} = F_{\text{abs}}(1 - \text{ER}_G)(1 - \text{ER}_H) \quad (19)$$

The hepatic extraction ratio (ER_H) can be determined after intravenous dosing from the ratio of hepatic clearance (CL_H) to hepatic blood flow (Q_H).

$$\text{ER}_H = \frac{\text{CL}_H}{Q_H} = \frac{f_u \text{CL}_{u,\text{int}}}{Q_H + f_u \text{CL}_{u,\text{int}}} \quad (20)$$

$$\text{So that } F_H = \frac{Q_H}{Q_H + f_u \text{CL}_{u,\text{int}}} \quad (21)$$

The ability to estimate the gut extraction ratio requires further experimental manipulations and assumptions, such as evaluating the effects of an enzyme inducer, e.g., rifampin, on oral and i.v. drug dosing as first utilized by Wu et al. (31) for cyclosporine, or measurement of portal concentrations as first utilized by Thummel and co-workers (19) for midazolam.

It is apparent that the greatest impact on oral bioavailability, that would result from the concerted activity of intestinal CYP3A and P-gp, will be observed in drugs that are characterized by low to intermediate hepatic first-pass extraction. High hepatic extraction will probably obscure the gut effects. The inhibition or induction of intestinal CYP3A directly translates into changes in the oral bioavailability of drugs. Inhibition and induction of P-gp in contrast, manifests as a change in the rate of absorption, T_{\max} , which can also affect the extent of oral availability, since the T_{\max} changes reflects the access of the drug to the intestinal enzymes.

Many commonly prescribed drugs are joint substrates for CYP3A and P-gp, which as has been discussed, both reside in the human intestine, associates within the enterocytes. It is therefore very likely that changes in bioavailability for a number of drugs could result from intestinal metabolism and/or efflux counter transport of absorbed drug back into the intestinal lumen. Selective inhibition of one or both of these processes could theoretically increase bioavailability, while decreasing the variability inherent in absorption. An approach using specific modifiers of intestinal metabolic and counter transport activity could conceivably transform the therapeutic efficacy of many drugs now in use.

DISTRIBUTION

The systemic circulation transports drug molecules from the site of administration to all tissues and organs in the body. Depending upon the physicochemical properties of the drug (lipophilicity, degree of ionization), the drug partitions into different tissues to different extents.

The rate at which distribution takes place into a tissue is dependent on both the drug partition coefficient (concentration in tissue/concentration in blood at equilibrium) and the blood flow to that tissue. The higher the perfusion rate (blood flow per unit volume of tissue), the more rapid is equilibrium achieved between blood and tissue. The higher the partitioning into the tissue, the longer reaching equilibrium takes, as more drug has to be transported to the tissue.

Within the blood, drug is dissolved in the plasma water (unbound concentration, C_u). Drug can also be bound to plasma proteins and concentrated in the red blood cells. It is the unbound drug molecules that diffuse across the membranes into the tissues. At equilibrium, the unbound concentration of drug is thought to be the same throughout the whole body.

Volume of Distribution

To measure drug concentrations, a blood sample is centrifuged and the plasma concentration analyzed. The relationship between the amount of drug in the body and the concentration (C) is called volume of distribution:

$$V = \text{amount in body} / C \quad (22)$$

Depending on the fluid being measured, blood (C_b), plasma (C_p) or plasma water (C_u), different values for the volume term can be obtained as the concentrations in these fluids differ.

The volume of distribution is a proportionality constant. It can be smaller or larger than the true physiologic fluid spaces of the body, depending upon whether the affinity of the drug is highest in plasma constituents or in other tissues. For a normal 70-kg man, the plasma volume is 3 liters, blood volume is about 5.5 liters, extracellular fluid outside plasma is 12 liters, and total body water is approximately 42 liters.

To determine the volume of distribution of a drug, an i.v. dose is necessary. The volume of distribution can be calculated from the plasma concentration versus time data by means of noncompartmental methods as described by Benet and Galeazzi (32) for a bolus i.v. dose

$$V_{ss} = \frac{\text{Dose}_{i.v.} \cdot \text{AUMC}}{\text{AUC}^2} \quad (23)$$

Here V_{ss} represents the volume in which a drug would appear to be distributed during steady state, AUC is the area under the plasma concentration time curve, and AUMC is the area under the first moment of the plasma concentration time curve, that is, the area under the curve of the product of time, t , and plasma concentration, over the time span zero to infinity. The volume of distribution at steady state can also be determined by compartmental methods, that is, by using the coefficients and exponents of a multiexponential fit to the data (33).

An alternative measure of volume of distribution is V_{area} . This parameter is dependent on the terminal half-life or, expressed differently, the terminal rate constant λ_z , where λ_z is equal to $0.693 / t_{1/2}$

$$V_{\text{area}} = \frac{\text{Dose}_{i.v.}}{\lambda_z \cdot \text{AUC}} = \frac{\text{CL}}{\lambda_z} \quad (24)$$

as $\text{Dose}_{i.v.} / \text{AUC} = \text{CL}$, according to Eq. 7a. Although V_{area} is a convenient and easily calculated parameter, the value of V_{area} can show differences when the half-lives differ, for example, between different patient populations, without a true difference in the distribution space. Contrary to V_{area} , V_{ss} is theoretically independent of changes in elimination. Thus, to determine whether a particular disease state is

Table 1 Pharmacokinetic parameters for cefamandole in normals and uremics

Parameter	Normals ^a	Uremics ^b	Significance
CL (ml/min kg)	2.81 +/- 0.98	0.115 +/- 0.023	$p < 0.05$

Data is +/- S.D.

^aData from Ref. (34).^bData from Ref. (35).

influencing the clearance process and/or the distribution of the drug, the V_{ss} volume term should preferentially be used. An example of the different conclusions that can be drawn, depending on which of these volume terms is used, is shown in Table 1. The pharmacokinetic parameters for cefamandole in six normal volunteers (34) and in three uremic patients (35) are compared. As cefamandole is almost exclusively eliminated via the kidneys, uremia results in a dramatic decrease in clearance (24-fold). The terminal half-life increases, but only by a factor of 11, resulting in more than a twofold difference in V_{area} between the two groups (Eq. 24). Based on these data, conclusions could be made that a decreased renal function not only influences the ability to excrete cefamandole but also results in a decrease in the distribution of the drug in the body. However, when comparing V_{ss} the conclusion is that no significant difference exists in the distribution of cefamandole between the two patient populations.

HALF-LIFE

Half-life is the "oldest" and best known of all pharmacokinetic parameters. It is a measure of the time required for the amount of drug in the body to decline to half of its value. Half-life is a useful measurement to determine the time to reach steady state for chronic dosing, or the time for the amount or concentration of drug to decline, for example, after an intoxication. To reach 90% of steady state or to eliminate 90% of the drug from the body takes 3.3 half-lives because 50% of the steady-state level is reached in one half-life, 75% in two, 87.5% in three, and 93.75% in four half-lives. The corresponding values hold for elimination of drug from the body.

Half-life can be readily determined from a plot of log plasma concentration versus time and was for many years considered to be the most important characteristic of a drug. Early studies examining drug disposition in disease states were compromised, by a reliance on half-life as a

sole measure of disposition changes. It is now appreciated that half-life is a secondary, derived parameter that relates to and depends on the primary parameters of clearance (CL) and volume of distribution (V) according to the following relationship in Eq. 25:

$$t_{1/2} \approx \frac{0.693 V}{\text{CL}} \quad (25)$$

Thus, to look at half-life only as a measure of, for instance, the effect of liver disease on drug pharmacokinetics is not sufficient, as a change in half-life can be caused by either a change in clearance or a change in volume of distribution. Furthermore, half-life may be unchanged in a particular disease state due to parallel changes in both V and CL.

Clearance and volume of distribution are two separate and independent characteristics of a drug. They are closely correlated with physiologic mechanisms in the organism (thereby the term primary parameters). Clearance defines the body's ability to remove the drug, that is, by metabolism or by renal or biliary excretion. Volume of distribution is a measure of the physical interrelationship between the drug and body constituents, such as binding to plasma proteins or partition into muscle, tissue, or fat.

PROTEIN BINDING

At steady state, the distribution of any drug in the body is dependant upon its binding to plasma proteins, blood cells and tissue receptors. Only unbound drug is capable of entering and exiting from plasma and tissue compartments. Therefore, an apparent volume of distribution can be expressed as follows (36),

$$V = V_p + V_{\text{TW}} \frac{f_u}{f_{u,T}} \quad (26)$$

where V_p represents the volume of plasma, V_{TW} is the volume of tissue fluid (nonplasma), f_u represents the

Table 2 Conditions that alter the concentration of two major plasma proteins

Plasma protein	Condition	Change in concentration
Albumin	Hepatic cirrhosis	Decrease
	Burns	
	Nephrotic syndrome	
	End stage renal disease	
	Pregnancy	
α_1 Acid glycoprotein	Myocardial infarction	Increase
	Surgery	
	Crohn's disease	
	Rheumatoid arthritis	
	Trauma	

(Adapted from Ref. 40.)

fraction unbound in plasma, and $f_{u,T}$ is the fraction unbound in tissue. Human plasma contains over 60 proteins. Albumin is the major component of this protein family responsible for the binding of most drugs in plasma. Acidic drugs bind primarily to albumin, the major drug-binding protein in plasma. Some acidic drugs bind with very high affinity, for example, furosemide, which is 98–99% bound and warfarin, which is 99.5% bound. Basic drugs bind to albumin with lower affinity but are more avidly bound to proteins like α_1 -acid glycoprotein and various plasma lipoproteins. These proteins have lower concentrations in plasma relative to albumin. Binding is therefore more easily saturable, as is the case with some drugs such as prednisolone and disopyramide, yielding fluctuations in the free fraction of drugs falling within the therapeutic plasma concentration range (6). Because the binding of drugs to plasma proteins and tissue binding sites is largely nonselective, many drugs with similar chemical properties can compete with each other for access to binding sites. The concern over the potential for adverse drug events based on competitive displacement from plasma protein binding sites has been overstated however. Indomethacin has been shown to markedly decrease warfarin binding to human serum albumin, in vitro (37). However, this in vitro drug interaction has not been confirmed by in vivo studies (38). Steady-state unbound drug concentrations in vivo are largely independent of factors which alter protein binding, unless a drug is very highly protein bound, for example, greater than 90% (39). A dynamic equilibrium exists between tissue and plasma stores of any drug. Binding at these sites is reversible and changes so rapidly that equilibrium is re-established within milliseconds. Therefore, changes in the free fraction of drugs brought about by competition with higher avidity ligands or saturable

kinetics are quickly compensated for by movement of drug from tissue stores into plasma, precluding the need for adjustment of dosage regimens.

Variation in plasma protein concentrations can occur secondary to decreased albumin concentrations associated with hepatic cirrhosis, and nephrotic syndrome (Table 2). Increased (α_1 -acid glycoprotein concentrations are associated with the stress response to disease states such as myocardial infarction, inflammatory disease, and postsurgically (41). A more relevant problem resulting from competition between drugs for plasma protein binding is the misinterpretation of the measured concentrations of drugs in plasma, as most assays are not able to differentiate between bound and unbound drug (42). Concentration-dependent binding of a drug to a plasma protein is expected when the total drug concentration approaches the protein concentration. For albumin this concentration is 0.6 mM, and for α_1 -acid glycoprotein in healthy individuals it is 0.015 mM, assuming that one drug molecule binds per protein molecule. For a drug with a molecular weight of 250, this corresponds to concentrations in plasma of 150 mg/L and 4 mg/L, for saturation of albumin and α_1 -acid glycoprotein, respectively.

**Influence of Protein-Binding
Changes on Volume of Distribution**

As is obvious from the relationship shown by Eq. 26, a drug which is characterized by a high degree of binding to plasma proteins (i.e., a low f_u) will exhibit a small volume of distribution. Decreases in albumin concentration, for example, may result in a decline in the fraction of drug bound to plasma proteins. The increased amount of unbound drug is then free to distribute to other tissues.

Unlike binding to plasma proteins however, binding to tissue receptors cannot be measured directly. This parameter is generally assumed to be constant. Again, from Eq. 26, this would appear to result in a volume of distribution increase. However, these changes are only important for drugs exhibiting a high degree of binding in plasma ($>90\%$) and an even higher degree of binding in the tissues, that is, drugs with a high volume of distribution. Changes in protein binding will not significantly affect volume of distribution for low V drugs. Note that changes in volume of distribution do not influence the steady-state relationship between dosing rate and average concentration (Eq. 5).

Influence of Protein-Binding Changes on Clearance

If we examine Eq. 12–14, we can see that for drugs with a low extraction ratio (i.e., chlordiazepoxide), Q_{organ} is much greater than $f_u \text{CL}_{\text{int}}$; clearance is then approximated by $f_u \text{CL}_{\text{int}}$. However in the case of a high extraction ratio drug (i.e. lidocaine), $f_u \text{CL}_{\text{int}}$ is much greater than Q_{organ} , and clearance approaches organ blood flow. Therefore, clearance of high extraction ratio drugs is perfusion rate limited, and not influenced by protein binding. Clearance of low extraction ratio drugs, in contrast to Eq. 14, is dependent upon both the fraction unbound and the intrinsic clearance (CL_{int}) of the metabolizing organ, for example, the liver.

THE CONCEPT OF EXPOSURE

Most pharmacokinetic theory has concentrated on explaining changes in clearance and bioavailability in terms of the parameters of intrinsic clearance, blood flow and fraction unbound (Eqs. 12 and 21). Yet the response of a patient to a dose or dosage regimen of a drug is dependent on the patient exposure to the drug, which is best characterized by AUC. Thus, it will be useful to consider the importance of individual parameters such as CL_{int} , Q and f_u in terms of exposure concepts. Consider first an intravenous dose of a drug where from Eq. 7a

$$\text{AUC} = \frac{\text{Dose}_{\text{i.v.}}}{\text{CL}} \quad (27)$$

and for a drug excreted exclusively by the liver substitution of Eq. 12 into Eq. (7a) yields

$$\text{AUC} = \frac{\text{Dose}_{\text{i.v.}}(Q_H + f_u \text{CL}_{\text{u,int}})}{Q_H f_u \text{CL}_{\text{u,int}}} \quad (28)$$

For a high extraction ratio compound ($f_u \text{CL}_{\text{u,int}} \gg Q_H$), exposure will be inversely dependent upon hepatic blood flow

$$\text{AUC} \approx \frac{\text{Dose}_{\text{i.v.}}}{Q_H} \quad (29)$$

while for a low extraction ratio compound ($Q_H \gg f_u \text{CL}_{\text{u,int}}$), exposure will be inversely related to fraction unbound and intrinsic hepatic clearance.

$$\text{AUC} \approx \frac{\text{Dose}_{\text{i.v.}}}{f_u \text{CL}_{\text{u,int}}} \quad (30)$$

However, for an orally administered compound exposure will also be a function of oral bioavailability

$$\text{AUC} = \frac{F_{\text{oral}} \text{Dose}_{\text{oral}}}{\text{CL}} \quad (31)$$

Substituting, Eq. 18 for F_{oral} , Eq. 21 for F_H , and Eq. 12 for CL into Eq. 30 above, and simplifying yields the following expression of exposure following an oral dose of a drug where elimination is via the liver.

$$\text{AUC} = \frac{F_{\text{abs}} F_G \text{Dose}_{\text{oral}}}{f_u \text{CL}_{\text{u,int}}} \quad (32)$$

Note that for oral dosing, exposure is inversely related to fraction unbound and intrinsic clearance for all drugs independent of whether they are low or high extraction ratio compounds.

Comparing Eq. 29 and 31 for a low extraction ratio drug where elimination is primarily hepatic, it is obvious that similar oral and i.v. doses will yield similar AUC values, unless the product of $F_{\text{abs}} F_G$ is low. A drug with $F_{\text{abs}} F_G \approx 1$, such as acetaminophen yields similar exposure following both oral and intravenous dosing, and also the variability of exposure will be similar for both routes, since the factors controlling variability, $f_u \text{CL}_{\text{u,int}}$, are the same in each case. Cyclosporine is an example of a low extraction ratio drug eliminated systemically by hepatic metabolism where exposure is markedly less following oral dosing vs. i.v., since $F_{\text{abs}} F_G$ is so low, in this case due to marked first pass gut metabolism as depicted in Fig. 4. For this drug we would expect variability in exposure to the oral drug to be greater than i.v., due to the addition of the $F_{\text{abs}} \cdot F_G$ differences.

Propranolol is a good example of a high extraction ratio drug where systemic elimination is almost completely hepatic. Although there is some gut metabolism for propranolol following oral dosing, it is not extensive ($F_G \gg F_H$). Fig. 5 depicts the predicted differences in exposure following i.v. (10 mg) and oral (80 mg) dosing for this high

Fig. 5 Plasma propranolol levels in 5 subjects after i.v. administration of 10 mg and oral administration of 80 mg to fasting subjects. Observe the much larger variability in plasma concentrations between individuals after administration via the oral route. (From Ref. 43.)

extraction ratio drug. Note in comparing Eq. 28 and 31 that exposure is less for the oral dose since $f_u CL_{u,int} > Q_H$. In addition, it is obvious from Fig. 5 that the variability following oral dosing is much greater than that following i.v. dosing. That is, hepatic blood flow from subject to subject shows much less variability than the intrinsic clearance of the hepatic enzymes.

Returning to pharmacodynamic considerations, it is generally believed that drug responses, both efficacious and toxic, are related to exposure of the patient to unbound concentrations of the drug. For intermittent (not continuous infusion) dosing of drugs, Eq. 1 can be written as

$$E = \frac{E_{\max} AUC_u^s}{AUC_{u,50}^s + AUC_u^s} \quad (33)$$

where $AUC_{u,50}$ is the unbound AUC that yields 50% of the maximal effect over a dosing interval. That is, the effect achieved over a dosing interval for a given dose of the drug is a function of the exposure to unbound concentrations of the drug. Unbound drug exposure is related to total exposure by f_u , fraction unbound.

$$AUC_u = AUC f_u \quad (34)$$

Note that unbound drug exposure will be independent of f_u for orally administered drugs that are predominantly eliminated by hepatic mechanisms. When AUC from Eq. 31 is substituted into Eq. 33 then

$$AUC_u = \frac{F_{\text{abs}} F_G \text{Dose}_{\text{oral}}}{CL_{u,int}} \quad (35)$$

Similarly for intravenous dosing of low extraction ratio drugs, AUC_u is independent of f_u . Substituting, Eq. 29 into Eq. 33 yields

$$AUC_u \cong \frac{\text{Dose}_{i.v.}}{CL_{u,int}} \quad (36)$$

For high extraction drugs predominantly eliminated by the liver, f_u does affect AUC_u

$$AUC_u \cong \frac{f_u \text{Dose}_{i.v.}}{Q_H} \quad (37)$$

For drugs where hepatic elimination is negligible, then $F_H = 1$ and following oral or intravenous dosing we may predict AUC_u as follows

$$AUC_u = \frac{f_u F_{\text{abs}} F_G \text{Dose}}{CL} \quad (38)$$

and for a drug eliminated by renal processes

$$CL = \frac{Q_K f_u CL_{u,int}}{Q_K + f_u CL_{u,int}} \quad (39)$$

where Q_K is blood flow to the kidney. Substituting Eq. 38 into Eq. 37, then

$$AUC_u = \frac{F_{abs} F_G \text{Dose}(Q_K + f_u CL_{u,int})}{Q_K CL_{u,int}} \quad (40)$$

For a low extraction ratio drug in the kidney ($Q_K \gg f_u CL_{u,int}$), Eq. 39 becomes

$$AUC_u = \frac{F_{abs} F_G \text{Dose}}{CL_{u,int}} \quad (41)$$

whereas for a high extraction ratio drug in the kidney ($f_u CL_{u,int} \gg Q_K$), Eq. 39 becomes

$$AUC_u = \frac{F_{abs} F_G \text{Dose} f_u}{Q_K} \quad (42)$$

Note from the equations above that f_u becomes a determinant of AUC_u , and its thereby effect, only for a high extraction ratio drug given intravenously when the liver is the major route of elimination (Eq. 36), and for a high extraction ratio drug given orally or intravenously when the kidney is the major route of administration (Eq. 41). Since most drug dosings do not fall into these very limited categories, it now becomes clear why changes in protein binding as a function of disease state or drug interactions are generally of irrelevant consequences.

NONLINEAR PHARMACOKINETICS

Most drugs fortunately show linear pharmacokinetics within the therapeutic plasma concentration range (that is, with a doubling of the dose, the plasma concentration is also doubled), making possible the prediction of the impact of changes in drug dosing on the pharmacokinetic outcome.

Nonlinear pharmacokinetics are caused mainly by saturation of the metabolizing enzymes during drug elimination or during the first passage of drug through the liver, and also by saturable protein binding as previously discussed. This leads to less predictable results in drug therapy and to the risk of a higher incidence of side effects.

Nonlinear Elimination/Clearance

All metabolic processes are saturable at a certain concentration of the substrate/drug. Thus, rate of elimination of the drug by metabolism as described by

Eq. 5 can also be described by a Michaelis-Menten equation:

$$\text{Rate of metabolism} = \frac{V_m C}{K_m + C} \quad (43)$$

From these equations metabolic clearance can be described as

$$CL = \frac{V_m}{K_m + C} \quad (44)$$

where V_m is maximal velocity and K_m is the Michaelis-Menten constant. When kinetics are linear, $C \ll K_m$, and clearance equals V_m/K_m , but as the concentration approaches or exceeds K_m , clearance becomes dependent on the concentration, resulting in saturable metabolism. At steady state, when input rate (R_{in}) equals elimination rate, the steady-state concentration can be described by replacing rate of metabolism in Eq. 42 by R_{in} and rearranging

$$C_{ss} = \frac{K_m R_{in}}{V_m - R_{in}} \quad (45)$$

Drugs that show saturable metabolism within the therapeutic range include phenytoin and salicylate. Because of the serious side effects encountered with phenytoin, and because of the genetic variability in metabolic capacity with respect to individual V_m and K_m values, phenytoin therapy is closely monitored using plasma concentration analysis. Phenytoin has a therapeutic concentration range of 10–20 mg/L, which is above K_m for most individuals. A small change of the dose in this region leads to a big change in plasma concentrations. An orbit graph of the relationship between V_m , K_m , and the average steady-state concentration of phenytoin based on Eq. 44 is shown in Fig. 6.

The mean values of K_m and V_m within the population are 4 mg/L and 7 mg/kg/day, respectively. The variation within the population is also depicted in Fig. 6, where 50% of the population has K_m and V_m values within the innermost circle, 75% within the second circle, and so on. With the help of this graph, the suitable dosing rate of phenytoin for an individual patient can be determined. With two plasma concentrations at two different dosing rates of phenytoin in one patient, his/her individual V_m and K_m values can be obtained to further optimize the dosing schedule.

Saturable first-pass effect

Because of very high drug concentrations entering the gut and the liver during the absorption of a drug after oral administration, the liver may often be exposed to drug concentrations that are much higher than after i.v. administration or much higher than the concentrations

Table 3 The extent of urinary excretion of *p*-Aminobenzoic acid and its acetyl metabolite as a function of rate and route of administration in one subject

Route	Total dose Na-PABA (g)	Total PABA in urine in 24 h as % of dose excreted in 24 h (%)	Acetyl-PABA in urine as % of total PABA (%)

	4	102	36
	8	102	30

(Adapted from Ref 46.)

encountered during the elimination phase after oral administration. These initial hepatic portal vein concentrations after oral administration may exceed K_m even if the plasma concentrations measured in a peripheral venous sample do not exceed K_m . The higher the dose, the more of the drug escapes first-pass metabolism, which gives higher bioavailability with increasing dose. An illustrative example of this is the availability of *p*-aminobenzoic acid (PABA) as shown in Table 3 (46). Virtually all PABA is eliminated into the urine as metabolite and unchanged drug within 24 h. However, the percent of the dose that has been metabolized to acetyl-PABA is dependent on dose size and rate of administration, with a clear decrease of the fraction of metabolite formed with increasing dose after oral administration. Also, the fraction of the dose that is metabolized increases dramatically with prolonged oral and i.v. administration. This may also have an impact on slow-release formulations, which for drugs exhibiting a saturable first-pass effect never yield portal vein concentrations as high as comparable immediate-release tablets, thus resulting in lower bioavailability for the slow-release formulation.

STEADY-STATE CONSIDERATIONS IN DESIGN OF DOSAGE REGIMENS

Most drug therapy is designed for chronic drug administration, such as for treatment of hypertension or

Fig. 6 The Bayesian feedback method of phenytoin dosage prediction. The eccentric circles represent the fraction of the sample population whose V_m and K_m values are within that orbit. By drawing lines from the measured C_{ss} values via the given doses of phenytoin, the most probable values of V_m and K_m can be estimated and further used in calculation of new dosing rates corresponding to a target concentration. (From Ref 44; also discussed in Ref 45.)

diabetes. At steady state, the rate of input equals the rate of elimination (cf. Eqs. 5 and 6):

$$\frac{F \text{ Dose}}{\tau} = CL C_{ss,avg} \quad (46)$$

where F is bioavailability, τ is the dosing interval, and $C_{ss,avg}$ is the average concentration during steady state. Note $C_{ss,avg}$ is another measure of exposure as discussed previously, since during the dosing interval $C_{ss,avg}$ is equivalent to AUC/τ . Multiplying both sides of Eq. 45 by τ and dividing by CL yields Eq. 30. From Eq. 45 dosing rate can be calculated knowing F and CL , or if $C_{ss,avg}$ is measured, CL/F can be estimated in a patient. Plasma drug concentration measurements as an aid in giving appropriate drug treatment may be useful when

1. The therapeutic index of the drug is low (e.g., theophylline, digoxin).
2. No pharmacodynamic measurements (e.g., blood pressure, minor side effects such as dry mouth during anticholinergic drug therapy) can be used as end points for therapy.
3. The drug shows nonlinear kinetics within the therapeutic range (e.g., phenytoin).
4. The patient is "uncommon" (e.g., newborns, small children, pregnant women, or patients with decreased kidney function).

For the average steady-state concentration, the frequency of drug administration is not important as long as the dosing rate is the same (Fig. 7). Thus, 1020 mg of theophylline can be given every 24 h or 340 mg every 8 h and still have the same average plasma concentration as when a constant infusion of 43.2 mg/h is given (17). However, the fluctuations around the mean value are influenced by the dosing interval. For drugs with a small therapeutic index, the fluctuations between maximum and minimum concentrations during a dosing interval must be kept within the therapeutic range, thus favoring shorter dosing intervals.

Maximum ($C_{ss,max}$) and minimum ($C_{ss,min}$) concentrations during a dosing interval τ can be estimated using the following equations, assuming rapid absorption compared to elimination, and a one-compartment model for the elimination, where λ is the rate constant for drug elimination:

$$C_{ss,max} = \frac{F \text{ Dose}/V}{(1 - e^{-\lambda\tau})} \quad (47)$$

In Equation (46) $(F \text{ Dose})/V$ describes what is added to the concentration from the new dose. Thus, ($C_{ss,min}$) may be

Fig. 7 Relationship between frequency of dosing and maximum and minimum plasma concentrations when a steady-state theophylline plasma level of 15 µg/ml is desired. The smoothly rising line shows the plasma concentration achieved with an intravenous infusion of 43.2 mg/h. The doses for 8-h administration are 340 mg; for 24-h administration, 1020 mg. In each of the three cases, the mean steady-state plasma concentration is 15 µg/ml. (From Ref 47.)

calculated as ($C_{ss,max}$) multiplied by the fraction remaining in the body at the end of the dosing interval:

$$C_{ss,min} = C_{ss,max} e^{-\lambda\tau} \quad (48)$$

The difference between maximum and minimum concentrations at steady state is $(F \text{ Dose}/V)$, and thus the amount that is eliminated during the dosing interval equals the available dose.

The factors that determine the average concentration at steady state are bioavailability and clearance. The maximum concentration is determined by the volume of distribution, the smaller the volume, the higher the concentration. The dosing interval compared to the half-life is most important in defining the fluctuations. A very convenient dosing interval is equal to the half-life of the drug. This results in a decline during the dosing interval to a minimum concentration that is 50% of the maximal concentration. However, administration of a drug every half-life might sometimes be difficult to achieve because of too short or too long half-lives compared to our 24-h cycle. A practical minimum dosing interval is 6 h, and the maximum is 24 h. For drugs with short half-lives,

slow-release preparations might give smoother plasma concentration curves and decrease the number of dosings required. Compliance ultimately determines the therapeutic outcome; therefore, adjusting drug dosings to the daily routine of an individual, as much as possible, is important.

Loading Dose

A loading dose is given to attain the effective target concentration rapidly. It can be given as one dose or, more commonly, be divided into several doses over a relatively short period of time, such as one per day. The size of the loading dose depends on the target concentration and the volume of distribution and bioavailability of the drug. The loading dose should give the same amount of drug as will be present in the body during steady state

$$\text{Loading dose} = C_{ss} V/F \quad (49)$$

A loading dose is used when the need for drug therapy is too urgent to wait 3–4 drug half-lives to reach the desired drug concentration in the body. The advantage is a more rapid attainment of steady state. The disadvantage is a higher risk of side effects if the drug concentrations become too high or if the individual is more sensitive to the drug than the average patient. However, in some instances, such as in dosing anti-arrhythmics following an acute myocardial infarction, the only choice is to give a loading dose.

INDIVIDUALIZING DOSAGE REGIMENS: INDIVIDUAL VARIATIONS AND DISEASE STATES

When starting a patient on a particular drug therapy, the clinician is dependent on general dosing information, such as from the PDR (Physicians Desk Reference) or other literature or experience, including an evaluation of the physical status of the patient. At that time the clinician cannot know exactly how this specific patient will react to the drug, pharmacokinetically or pharmacodynamically. For optimal therapy, the progress of therapy should be followed with measurements of relevant effect parameters, by titrating the dose to avoid certain known side effects, or by using therapeutic drug monitoring (drug plasma concentration measurements).

The need for individualized dosage recommendations has received increased attention in recent years parallel to the increased knowledge of what can cause interindividual variability in pharmacokinetic handling of drugs and in pharmacodynamic response. These causes include the

influences of genetic variations, age, and disease states. Disease states influence the pharmacokinetics of drugs mainly by impairing drug transport and/or elimination, such as in heart failure or kidney or liver disease.

Kidney function and age show a close correlation. Glomerular filtration rate (GFR) is 100–125 ml/min/70 kg at 20–30 years of age, and then declines approximately 1 ml/min per year as the patient ages. Decreased kidney function as a result of disease is usually detected by measuring serum creatinine levels and calculating the creatinine clearance as a measure of GFR, even though using creatinine as a marker for decreased kidney function has received increased criticism due to overestimation of GFR at medium–low kidney function (48). A GFR between 20 and 50 ml/min indicates moderate renal failure, and values <10 ml/min indicate severe renal failure. If a major portion of the dose of a drug is eliminated unchanged via the kidneys, or if active or toxic metabolites are renally eliminated, corrections for kidney function may be necessary in dosing recommendations.

The influence of age on metabolic clearance is less clear than its influence on renal function. Metabolic clearance is more variable between individuals because of the genetic control and the influence of environmental factors on the metabolic capacity. The term metabolism also encompasses many different enzyme reactions that might be influenced to different extents by age, liver disease, or genetic variables. Unlike renal disease, in which creatinine clearance provides a reasonable estimate of kidney function, not one good indicator exists for the degree of liver function impairment with respect to drug metabolizing capacity.

Liver disease includes many diverse conditions. A distinction can be made between acute and chronic liver disease with respect to changes in clearance. Acute states do not generally seem to influence metabolic clearance of most drugs, but chronic states, such as cirrhosis, seem to decrease metabolic function to a greater degree. Also in cirrhosis, a portion of the blood flow may be shunted past the small capillaries within the liver or bypass the liver, causing even less exposure of the drug to the metabolizing enzymes and thereby greatly increasing the bioavailability of high-extraction-ratio drugs. Different drugs show different behavior with respect to the influence of liver disease on pharmacokinetics. Oxidative pathways seem to be more highly affected by liver disease than conjugation reactions such as glucuronidation. This is evident in the benzodiazepine group, where in cirrhosis patients oxazepam and lorazepam are preferred over diazepam and chlordiazepoxide due to the smaller changes in clearance for the former drugs, which are predominantly glucuronidated (49).

Cardiac failure may influence drug disposition by decreasing the cardiac output and increasing the peripheral resistance, thereby redistributing the blood flow from peripheral organs and tissues, such as kidneys and muscles, in favor of central organs, such as brain and heart. This might cause a slower than normal distribution of drug throughout the body and higher initial concentrations in the central organs that could cause an increased risk of side effects. Because of a lower blood flow to the gastrointestinal tract, heart failure might cause a slower rate of absorption of drugs. However, this seldom results in a lower bioavailability. A decreased and redistributed blood flow in liver and kidneys could yield a slower elimination of highly extracted drugs (50).

Pharmacogenetics

The 20th century yielded an enormous expansion in the chemical arsenal available to medical professionals, for the treatment of disease. The worldwide use of these drugs, particularly over the past several decades, has revealed substantial interindividual differences in the response to drugs. These differences, confirmed and explained by pharmacokinetic analysis, appear in individual patients as variations not only in expected therapeutic responses, but often in the frequency and nature of associated adverse events. Any particular drug or drug dose may be therapeutic in some patients, but ineffective in other individuals. Along the same lines, some individuals may experience drug related adverse effects from standard therapy, while others are unaffected. Recognition of these interindividual differences in drug response is an essential first step in optimizing drug therapy. A great deal of evidence has accumulated over the past several decades indicating that a substantial portion of the observed variability in response to drugs is genetically determined, although age, nutrition, health, and environmental factors play important roles. Pharmacogenetics is primarily concerned with the genetic basis underlying this interindividual drug response, and focuses on genetic differences among individuals, and on the different patterns of drug response among geographically and ethnically distinct populations. The goal of pharmacogenetics is to make truly individualized drug therapy, one could say personalized medicine, possible, and with a reasonably predictive outcome.

The basic unit of inheritance is the *gene*, a specific DNA sequence of base pairs which codes for a particular protein. The *genotype*, is the configuration of genes in an individual, while the *phenotype*, is the outward physical expression of those genes. The mode of inheritance of any individual trait

can be either monogenic or polygenic, depending on whether it is derived from a single gene at a single locus (position), or by multiple loci on the chromosomes respectively. An *allele* is one, two or more different forms of the same gene, containing specific inheritable differences, occupying corresponding positions on paired chromosomes. *Genetic polymorphism*, refers to monogenic traits existing in the population in at least two phenotypes, each of which exists at a frequency of at least 1%. An individual possessing a pair of identical alleles for a given trait is said to be *homozygous* for that trait. Individuals who are *heterozygous* for a given trait, possess a combination of dominant and recessive alleles for that trait.

The cytochrome P450 (CYP) monooxygenase system of enzymes is responsible for the primary portion of xenobiotic (foreign substance) metabolism in man. This large family of genes is composed of numerous subtypes, among which CYP2D6, CYP3A4/3A5, CYP1A2, CYP2E1, CYP2C9 and CYP2C19 play especially important roles in genetically determined responses to a wide spectrum of drugs. Examples to date of inherited variability in pharmacokinetics have been almost entirely restricted to drug metabolism. Renal clearance for any drug tends to be very similar for age and weight matched patients in good health. Similarly, the role of genetics in determining the absorption and distribution of drugs is poorly defined.

A number of examples of genetic polymorphisms in drug metabolism have now been identified, involving oxidation, S-methylation, and acetylation., as shown in Table 4. These polymorphisms were initially identified by adverse drug reactions occurring in distinct groups, termed "poor metabolizers," following normal therapeutic doses of the initial, archetypic drugs.

Patients who are homozygous for the CYP2D6 "slow" alleles exhibit a poor metabolizer phenotype, with impaired metabolism and excretion of many drugs, such as metoprolol, nortriptyline and propafone (51). These "poor metabolizers" are more likely to experience adverse reactions to standard doses of these drugs. The frequency of this recessive trait ranges from 1–2% in Asians, approximately 5% in African Americans to 6–10% in Caucasian populations (52). More than 40 drugs now in clinical practice, particularly in the areas of cardiovascular disease and psychiatric disorders exhibit the same polymorphic pattern of metabolism by CYP2D6 (53, 54). Along similar lines, patients who are homozygous for the recessive allele of CYP2C19 are highly sensitive to omeprazole, diazepam, propranolol, mephennitoine, amitriptyline and other drugs metabolized by this isoform (51). The "poor metabolizer" phenotype of CYP2C19 comprises approximately 2–5% of Caucasians

Table 4 Polymorphic drug metabolizing enzymes

Enzyme	Variant phenotypes	Drugs	Modified response
Plasma pseudocholinesterase	Slow hydrolysis	Succinylcholine	Prolonged apnea
Acetyl transferase NAT2	Slow, rapid acetylators	Isoniazid Sulfamethazine Procainamide Sufasalazine Paraminosalicylic acid Hydralazine	Toxic neuritis, lupus erythematosus. (Slow acetylators)
Thiopurine methyltransferase	Poor TPMT methylators	6-Mercaptopurine 6-Thioguanine Azathioprin	Bone marrow toxicity, hepatotoxicity
Dihydropyrimidine dehydrogenase	Slow inactivation	5-Fluorouracil	Enhanced toxicity
Aldehyde dehydrogenase	Fast, slow metabolizers	Ethanol	Slow: facial flushing Fast: protection from liver cirrhosis
CYP 2D6	Rapid, poor metabolizers	Debrisoquine Sparteine Phenformin Nortriptyline Dextromorphan, etc.	Poor: increased toxicity Rapid: drug resistance
CYP 2C9	Poor metabolizers	Tolbutamide S-warfarin Phenytoin Nonsteroidal anti-inflammatory agents Imipramine	Increased response or toxicity
CYP 2C19	Poor and extensive hydroxylators	Mephenytoin Hexobarbital Omeprazole Proguanil, etc.	Poor: increased toxicity Extensive: drug resistance

and 3–23% of Asians. Another polymorphically expressed enzyme of the P450 superfamily is CYP2C9. This enzyme is responsible for the metabolism of a range of therapeutically important drugs such as phenytoin, tolbutamide and warfarin (5). It has been estimated, that approximately 5% of Caucasians possess the genetic variant of CYP2C9 associated with a fivefold decline in metabolic activity (6). Drugs such as phenytoin and warfarin, for example, have narrow therapeutic indices, and individual genetically based variations in metabolism could have important clinical significance.

Individuals also vary widely in their elimination kinetics of isoniazid, procainamide, and other substrates of N-acetyltransferase (NAT2). Peripheral neuropathy associated with the use of isoniazid, an antituberculosis drug, first surfaced more than 40 years ago. It is now known that the “slow acetylator” phenotype represents

approximately 40–50% of Caucasians, and results in decreased clearance of drug with increased potential for associated toxicities.

Genetic heterogeneity appears then, to be an important source of the observed variability in drug response. This strongly implies that information pertaining to interethnic and interindividual genetic differences can play an important role in drug discovery and development. New genetic tools for the rapid, inexpensive determination of patient genotypes could have important therapeutic implications. The need for a new, individualized approach to drug therapy is now, more obvious than ever. Every year approximately 3 billion prescriptions are issued in the United States, of which 2 million result in an adverse reaction, with as many as 1 million resulting in hospitalization. Some 100,000 patients die each year as a result of drug induced adverse

reactions. Early or preventive therapy, guided by individual genetic information, could significantly improve clinical outcomes, while reducing the incidence of drug associated adverse events.

USE OF PHARMACOKINETIC INFORMATION IN DRUG FORMULATION

Depending on the use of a drug, different parameters are important in designing a dosage form. For intermittent drug use, such as aspirin for headache, the ideal dosage form should give a rapid rate of absorption to yield quick relief of the pain. This objective has led to the formulation of buffered or soluble forms of acetylsalicylic acid, for which the absorption rate is limited mainly by the drug's ability to cross the GI membranes. With a different indication, such as aspirin used chronically for rheumatoid arthritis, low exposure to the stomach is desired; for this purpose, enteric-coated tablets and granules of the drug have been formulated.

For a drug intended to be used chronically, the clearance of the drug from the body, together with the extent of availability, determines the dose size for a given therapeutic drug level (Eq. (45)). If clearance and volume of distribution of the specific drug result in a short half-life and keeping drug concentrations above a certain level is important, for example, during antiarrhythmic treatment, the dosing interval is crucial, leading to the demand for a controlled-release dosage form.

However, pharmacokinetic properties of a drug may pose limitations as to the possibility of attaining an ideal therapy. The choice of digoxin over digitoxin is mainly determined by the shorter half-life and in the minds of some clinicians a safer and more predictable drug therapy with digoxin. Oxazepam is an example of a drug with a slower than wanted rate of absorption, which decreases its use as a help in starting to sleep. This slow absorption rate is a characteristic of the drug itself and cannot be increased by drug-product formulation. Thus, dosage form development is limited by the basic pharmacokinetic properties of the drug.

The oral bioavailability of a high-extraction-ratio drug can never be improved by dosage form development if the reason for low availability is high first-pass metabolism. The ability to give an oral dosing regimen of a high-extraction-ratio drug is dependent on the ratio between therapeutic concentrations of the drug and toxic concentrations of the metabolites formed during the first pass and on how critical for successful therapy staying

within the therapeutic range of drug concentrations is. Both lidocaine and propranolol have a high extraction in the liver with low bioavailability as a result (35 and 36%, respectively) (6). However, propranolol is given orally and lidocaine is not. Therapeutic concentrations of lidocaine are 1.5–6 mg/L, and side effects start to appear at concentrations of 6–10 mg/L. For lidocaine falling below the therapeutic concentration range is just as serious as going too high in concentration, as both situations may cause arrhythmias. With a half-life of only 1.8 h, oral doses would have to be given very often, which is not practical. Also, the variability in the first-pass effect between individuals (Figs. 4, 5) makes uniform dosing recommendations difficult. Propranolol also has a relatively short half-life (3.9 h), but the therapeutic index is much higher, and plasma concentrations falling below the "therapeutic concentration" are not as critical for the patient; therefore, larger fluctuations in plasma concentrations can be allowed during a dosing interval without loss of an acceptable therapeutic outcome.

The pharmacokinetic profile of a drug can in this way be used as a basis for dosage form development, together with the specific requirements of the particular drug concerning maximal and/or minimal concentrations desired, effectiveness versus toxicity, the desired rate of attaining an effect, and the convenience of drug administration for the individual.

Thus, the knowledge of basic pharmacokinetic features, such as rate of absorption, degree of absorption, degree of renal elimination versus metabolism, whether the drug is a high or a low extraction drug, and the like, and knowledge of the pharmacokinetic–pharmacodynamic relationship are tools in optimizing drug product development to the needs of the patient.

INTRODUCTION

The process of developing a new drug, from the identification of a potential drug candidate to postmarketing surveillance, is extremely complex. The drug development process requires input from various members of a multidisciplinary team and the conduct of numerous studies. The time from drug discovery to marketing takes an average of 13 years. Once a chemical is identified as a new drug candidate, extensive preclinical analyses must be completed before the drug can be tested in humans. The pharmacology, toxicology, and preclinical pharmacokinetics must be characterized. The formulations of the drug product that were used in the preclinical studies may be different from the formulation of the final drug product, which may require that additional formulation work and pharmacokinetic analyses be performed. If the characteristics of the new drug candidate are acceptable for all of the preclinical assessments, it may then be tested in humans. The new drug candidate, at this point, enters the clinical research stage of drug development.

Clinical research represents a vital stage in the development process a stage that is no less daunting than the preclinical research stage. The data obtained from the first-time-in-human, Phase 1 pharmacokinetic studies, and initial safety evaluations in healthy volunteers can make or break the entire developmental program for a drug candidate. The sponsoring company, of course, hopes that the data collected in these initial studies will show minimal safety concerns over an adequate dose range. The pharmacokinetic data can then be used to help design future studies in which efficacy and long-term safety are assessed and additional pharmacokinetic and pharmacodynamic data are collected.

Although the basic designs of the initial single and multiple dose-escalating studies are generally straightforward (but the starting dose is often intensely debated), it is imperative that these studies and future studies be

designed to address specific questions. The questions vary depending on numerous specific considerations, including the targeted disease characteristics (e.g., acute or chronic); desired safety, efficacy, and pharmacokinetic evaluations; and assessment of clinical pharmacology (e.g., dosage formulations or dose frequency). Basic study procedures must also be considered. Thus, the design, conduct, data reporting and analysis, and production of the final study reports can be completed only through the coordinated efforts of a multidisciplinary drug development team.

For every clinical study, input is required from multiple personnel with various areas of expertise. Members of a drug development team include physicians, scientists, pharmacists, project managers, statisticians, computer programmers, study monitors, regulatory experts, and for some studies, a representative of the formulations group. While some team members may be able to perform multiple tasks, no one team member has the expertise or the time to do everything required to conduct a clinical study. In addition, some members may have overlapping abilities, but other members with particular expertise may be called upon. For example, pharmacokineticists are the experts in pharmacokinetics, but they may also be knowledgeable in pharmaceutics, biostatistics, and clinical care. However, scientists (PhDs) are trained primarily in basic research, while physicians (MDs) are trained in clinical medicine. Since a single drug development program is derived from both of these distinct disciplines, considerable overlap, cooperation, and coordination are necessary to take a drug successfully and efficiently from discovery to market.

Clinical drug development is generally divided into four phases: Phase 1 through Phase 4. For each study conducted within a particular phase, specific information is collected according to the requirements for individual drugs being developed. Collection of safety, efficacy, and pharmacokinetic data is the focus of most clinical trials. Although these topics appear to be distinct disciplines,

they are intertwined and represent different ways of evaluating the intrinsic properties of a drug. While the safety, efficacy, and pharmacokinetics of a drug may be assessed in most studies, the team must establish the type and extent of information to be collected, which will vary based upon the specific objectives and designs of the studies.

A critical function of the drug development team is the development of the study protocol. The study protocol must clearly describe the study design and methodology that will be used to achieve the study objectives. Input from nonmedical and nonscientific members of the team, such as marketing and information technology experts, also is helpful in establishing development strategies and in designing and conducting of clinical studies. Finally, project planning efforts can synchronize team efforts, help contain the soaring costs of pharmaceutical research, and coordinate international development efforts.

The drug development team's primary goal is to gain approval to market the drug, which requires that a marketing application be submitted to a regulatory agency (e.g., a New Drug Application [NDA] is submitted to the Food and Drug Administration [FDA] in the United States and to the Health Products and Food Branch [HPFB] in Canada, while a Marketing Authorization Application [MAA] is submitted to European regulatory agencies). During the conduct of the studies and the compilation and analyses of the data, the team must consider and evaluate many issues, such as how to collect, categorize, and report adverse events. All of these decisions will affect the marketing application that is submitted and may ultimately define how the drug is to be administered.

Many of the decisions to be made by the team, and particularly by the investigators, pose ethical dilemmas. Legislation has been enacted to protect human research subjects. Recently, the most pressing ethical dilemma facing the clinical research scientist concerned biotechnology and genetic engineering research.

Frequent changes in the regulations and guidelines of various regulatory agencies, differences in interpretations of these rules, and special reporting mechanisms for adverse events represent only a few of the challenges facing a drug development team. Due to continuous advances in scientific information, understanding of disease processes, and gene therapy, change continues to be the rule in modern drug development. However, through the efficient application of sound scientific principles in an ethical manner and with a coordinated team effort, effective new therapies can continue to be developed and marketed.

ROLES OF THE DRUG DEVELOPMENT TEAM MEMBERS

Physicians

The physician's contribution to drug development and the physician's role on a drug development team have changed over the last few decades (1). Before the 1960s, medical departments of pharmaceutical companies were primarily composed of physicians who were routinely involved in responding to drug information requests rather than developing new drugs. The Kefauver–Harris Amendment, enacted in 1962, required pharmaceutical companies to demonstrate before marketing that a drug was efficacious, which necessitated that physicians increase their presence on drug development teams. Along with the advent of additional governmental regulations, the increase in complexity of medical knowledge has mandated that physicians become an integral member of any drug development team. In fact, because of the different roles of the physician within an organization, companies may now have various departments (e.g., a clinical research department and a clinical safety department) within the medical department.

Although physicians are trained in patient care, physicians who are typically employed by pharmaceutical companies have more training in scientific methodology than those in the past. The physician on the team is the one qualified to follow the progress of each patient enrolled in a clinical trial and to interpret the results. Some physicians continue to spend time treating patients at a university hospital or a specific clinic where their specialty can be utilized and practiced, which allows these physicians to maintain sharp diagnostic skills. Also, some may perform basic research in academic settings to develop or maintain their knowledge and skills in basic research.

However, much of today's clinical research is actually conducted by investigators who are not employed by the company sponsoring the development of the drug. The physician on the drug development team must help in the selection of appropriate investigators to conduct the clinical studies. Pharmaceutical physicians may rely on colleagues who are experts in their respective fields and who have appropriate patient populations and facilities for the targeted research project. The physician is also the expert who deals with emergency situations that may arise during the course of a clinical research project, such as an overdose or severe adverse experience (SAE) that might be experienced with the drug. Similarly, the physician assists investigators who are responsible for evaluating the severity of adverse experiences (AEs) and determining

the causal relationship of the AEs to the drug under development.

The physician's involvement in clinical research does not end with the completion of the clinical study. Medical reports, clinical study reports, and sections of NDAs must be written. Interactions with regulatory agencies that require the physician's input may occur frequently. Physicians in clinical research may also be called upon to promote new drugs in a scientific environment by organizing symposia and workshops and by reviewing journal advertisements and promotional material for medical validity and accuracy.

The role of the physician in a clinical drug development program has expanded and has been refined in the last 40 years. Physicians increasingly contribute clinical and scientific expertise and administrative skills. Many physicians on drug development teams today spend most of their time designing and implementing studies and interpreting and reporting data rather than being in direct contact with patients. An experienced clinician is an important member of any drug development team.

Scientists

While a drug development team may have only one primary physician, it may have multiple scientists. Pharmacokineticists, pharmacologists, toxicologists, and pharmaceutical scientists are all involved in the clinical development of drugs. The contributions of scientists to a drug development project are derived from their experience in both scientific methodology and basic research (1).

Although physicians are trained in patient care, scientists are trained in problem-solving skills related to scientific research. To obtain a doctoral degree, a scientist must conduct research and write a dissertation that covers a topic of sufficient scope and depth. During this process, the scientist learns how to solve problems from different perspectives. The scientist also collects extensive data and performs data analyses, thereby gaining valuable insight into the considerations necessary to determine the feasibility of collecting data in a clinical trial. Also, some scientists, such as pharmacokineticists with a pharmacy background, may receive some clinical experience during their training as a scientist.

Scientists help design major portions of study protocols and clinical case report forms (CRFs). The study protocol is the overall plan that the study follows, and it must contain certain types of information, including the following: 1) background data on the targeted disease; 2) the empirical and structural formula of the drug being

studied; 3) preliminary pharmacology and toxicology of the drug (specific study objectives and designs); 4) the methods and materials to be used in the study; 5) information regarding drug packaging, labeling, dosage forms, and decoding procedures; 6) overdose management; 7) patient discontinuation procedures; 8) explanation of informed consent and provisions regarding institutional review board approval; and 9) any relevant references and appendices. The CRFs are the forms on which individual patient data are recorded during a clinical trial. From these data, clinical and statistical analyses are performed. All the information that is stipulated in the study protocol must be collected on the CRFs.

In conjunction with nonscientific personnel, scientists are responsible for ensuring that the CRFs will capture the appropriate information for each study subject according to the objectives, tests, and evaluations stipulated in the protocol. Careful attention must be given to the administration of special tests or collection of samples so that the timing of the assessments or sample collections do not conflict.

Experience in basic research enables the scientist to function as an important link between the basic research labs within the company and the drug development team. Departments specializing in drug metabolism, microbiology, pharmacology, and toxicology need feedback from early human safety and pharmacokinetic studies so they can continue to plan and conduct appropriate long-term animal studies. Thus, communication between the clinical scientist and the basic scientist is important throughout the progress of the drug development program.

Because clinical research has become increasingly more scientific, experts in the methodology of science are necessary for a complete research program. The drug development team's scientists may account for much of the scientific expertise, but the roles of the research team overlap to form a scientifically sound, medically astute cohesive group. In addition to scientific expertise, use of the scientist's administrative talents, such as organizational skills and familiarity with personnel practices, enables effective drug development. Thus, scientists with these skills are often employed in management positions in many organizations.

Pharmacists

The pharmacist's role on the drug development team has greatly expanded the professional opportunities of individuals with backgrounds in pharmacy. Pharmacists can provide valuable therapeutic insight into medical research. Training of pharmacists as clinical scientists with

both clinical skills and scientific research skills continues to be an emphasis at many pharmacy schools. Several programs have been devised for the education and development of the pharmacist as clinical scientist (2). Pharmacists have a broad knowledge in both clinical medicine and pharmaceuticals, and therefore are able to bridge the gap between the clinic and the laboratory.

Pharmacists' training focuses on drug therapies in disease states, whereas physicians' training focuses on the diagnosis of disease states. Studies regarding drug interaction, positive control, or drug comparison involve drugs that have been studied and marketed. Pharmacists can help in the design of such trials because of their knowledge of marketed drugs.

Additional roles of pharmacists appear in the areas of drug information and education and training. Pharmacists have the appropriate expertise in drug therapy to answer inquiries from physicians (and other health professionals) concerning both marketed and investigational drug products. Similarly, the clinic/laboratory bridge that the pharmacist builds makes this team member especially well suited to educate and train new employees in drug development. By offering both general and special skills, the research pharmacist blends clinical medicine with pharmaceutical science and is well qualified as an educator and drug information specialist.

Nonscientific Personnel

Drug development includes many tasks that may not require the specialized expertise of a physician or a scientist. Administrative skills, creativity, and excellent communication abilities, which are qualities not necessarily emphasized within traditional medical and scientific educational curricula, may be required for many of these tasks.

The administrative skills necessary for drug development include incorporating seemingly disparate but vitally linked concepts into a single overall plan. Integration planning may mean organizing study files into a logical sequence or helping to assemble the various parts of an NDA. In the first example, files must be set up in a way that can facilitate internal quality assurance audits and FDA inspections. In the second example, knowledge of the FDA's regulations and good abstracting capabilities are required.

Creativity is a quality that cannot be developed through formal training. Creativity requires bold conjecture and it expresses itself in newer, better ways to accomplish the same goals. An example of creativity in clinical drug research might involve the development of a variable

report that could support all of the different research documents that are generated by drug research teams. With such a variable report, common information need not be recreated each time another document is generated.

Excellent communication skills may be the most important quality for individuals working in drug development, even for those with strong medical backgrounds. Clinical research requires extensive interactions with personnel within the organization and with outside vendors or clinical sites. The information flow must be both efficient and accurate. For example, marketing departments must communicate frequently with medical departments so that marketing studies, advertising, and package inserts can be planned and evaluated. Individuals who lack strong science backgrounds but who have excellent communication skills often act as liaisons in these situations.

One aspect of clinical research that requires extensive contribution by the drug development team personnel is study monitoring. Study monitors oversee the planning, initiation, conduct, and data processing of clinical studies (3). While monitoring studies, monitors must communicate frequently with investigators and help ensure the data are being collected properly, FDA regulations are being followed, and any administrative problems are resolved as quickly as possible. Although monitors traditionally have had a nonscientific background, many monitors today have training in the basic sciences, and some even have advanced degrees, which allows them to better understand the scientific aspects of the project. Effective study monitors have a wide range of talents.

The many facets of a clinical research program afford individuals with varying types of training, education, and experience, the opportunity to contribute to the drug development process. Although some tasks clearly require the clinical or scientific expertise of a physician or a scientist, other tasks are better suited to those individuals with less specialized and more general capabilities.

STAGES IN CLINICAL DRUG DEVELOPMENT

Before clinical drug development can begin, many years of preclinical development occur, millions of dollars are spent, and countless decisions are made. Basic research teams consisting of chemists, pharmacologists, biologists, and biochemists first identify promising therapeutic categories and classes of compounds. One or more compounds are selected for secondary pharmacology evaluations and for both acute and subchronic toxicology testing in animal models. A compound that is

pharmacologically active and safe in at least two nonhuman species may then be selected for study in humans. Before the drug can be tested in humans, an Investigational New Drug (IND) application, which contains supporting preclinical information and the proposed clinical study designs, must be filed with an appropriate regulatory agency.

Clinical drug development follows a sequential process. By convention, development of a new drug in humans is divided into four phases: preapproval segments (Phases 1 through 3) and a postapproval segment (Phase 4) (1–4). The definitions of the three preapproval phases have relatively clear separations. However, the different phases refer to different types of studies rather than a specific time course of studies. For example, bioequivalence studies and drug–drug interaction studies are both Phase 1 studies, but they may be conducted after Phase 3 studies have been initiated. The generalized sequence of studies may be tailored to each new drug during development.

Phase 1

After the appropriate regulatory agency has approved a potential drug for testing in humans, Phase 1 of the clinical program begins. The primary goal of Phase 1 studies is to demonstrate safety in humans and to collect sufficient pharmacokinetic and pharmacological information to permit the determination of the dose strength and regimen for Phase 2 studies.

Phase 1 studies are closely monitored, are typically conducted in healthy adult subjects, and are designed to meet the primary goal (i.e., to obtain information on the safety, pharmacokinetics, and pharmacologic effects of the drug). In addition, the metabolic profile, adverse events associated with increasing dosages, and evidence of efficacy may be obtained. Because most compounds are available for initial studies as an oral formulation, the initial pharmacokinetic profile usually includes information about absorption. Additional studies, such as drug–drug interactions, assessment of bioequivalence of various formulations, or other studies that involve normal subjects, are included in Phase 1.

Generally, the first study in humans is a rising, single-dose tolerance study. The initial dose may be based on animal pharmacology or toxicology data, such as 10% of the no-effect dose. Doses are increased gradually according to a predetermined scheme, often some modification of the Fibonacci dose escalation scheme (5), until an adverse event is observed that satisfies the predetermined criteria of a maximum tolerated dose (MTD). Although the primary objective

is the determination of acute safety in humans, the studies are designed to collect meaningful pharmacokinetic information. Efficacy information or surrogate efficacy measurements also may be collected. However, because a multitude of clinical measurements and tests must be performed to assess safety, measurements of efficacy parameters must not compromise the collection of safety and pharmacokinetic data.

Appropriate biological samples for pharmacokinetic assessment, typically blood and urine, should be collected at discrete time intervals based upon extrapolations from the pharmacokinetics of the drug in animals. Depending on the assay sensitivity, the half-life and other pharmacokinetic parameters in healthy volunteers should be able to be evaluated, particularly at the higher doses. The degree of exposure of the drug is an important factor in understanding the toxicologic results of the study. Pharmacokinetic linearity (dose linearity) or nonlinearity will be an important factor in the design of future studies.

Once the initial dose has been determined, a placebo-controlled, double-blind, escalating single-dose study is initiated. Generally, healthy male volunteers are recruited, although patients sometimes are used (e.g., when testing a potential anticancer drug that may be too toxic to administer to healthy volunteers). These studies may include two or three cohorts, with six or eight subjects receiving the active drug and two subjects receiving placebo. The groups may receive alternating dose levels, which allow assessment of dose linearity, intrasubject variability of pharmacokinetics, and dose-response (i.e., adverse events) relationship within individual subjects.

Participants in the first study are usually hospitalized or enrolled in a clinic so that clinical measurements can be performed under controlled conditions and any medical emergency can be handled in the most expeditious manner. This study is usually placebo-controlled and double-blinded so that the drug effects, such as drug-induced ataxia, can be distinguished from the nondrug effects, such as ataxia secondary to viral infection. The first study in humans is usually not considered successfully completed until an MTD has been reached. An MTD must be reached because the relationship between a clinical event (e.g., emesis) and a particular dose level observed under controlled conditions can provide information that will be extremely useful when designing future trials. Also, the dose range and route of administration should be established during Phase 1 studies.

A multiple-dose safety study typically is initiated once the first study in humans is completed. The primary goal of the second study is to define an MTD with multiple

dosing before to initiating well-controlled efficacy testing. The study design of the multiple-dose safety study should simulate actual clinical conditions in as many ways as possible; however, scientific and statistical validity must be maintained. The inclusion of a placebo group is essential to allow the determination of drug-related versus nondrug-related events. The dosing schedule, which includes dosages, frequency, dose escalations, and dose tapering, should simulate the regimen to be followed in efficacy testing.

Typically, dosing in the second study lasts for 2 weeks. The length of the study may be increased depending on the pharmacokinetics of the drug so that both drug and metabolite concentrations reach steady state. Also, if the drug is to be used to treat a chronic condition, a 4-week study duration may be appropriate. To obtain information for six dose levels with six subjects receiving active drug and two receiving placebo for each of two cohorts, a minimum enrollment of 24 subjects should be anticipated. Similar to the first study in humans, these subjects would be hospitalized for the duration of the study.

Also similar to the first study, pharmacokinetic data must be obtained. These data will be used to help determine dosage in future efficacy trials. The new pharmacokinetic information that can be gathered includes the following: 1) determination regarding whether the pharmacokinetic parameters obtained in the previous acute safety study accurately predicted the multiple dose pharmacokinetic behavior of the drug; 2) verification of pharmacokinetic linearity (i.e., dose proportionality of C_{\max} and AUC) observed in the acute study; 3) determination regarding whether the drug is subject to autoinduction of clearance upon multidosing; and 4) determination of the existence and accumulation of metabolites that could not be detected in the previous single-dose study. A number of experimental approaches can be used to gather this information, and all require frequent collection of blood and urine samples. The challenge to the clinical pharmacokineticist is to design an appropriate blood sample collection schedule that will maximize the pharmacokinetic information, yet can be gathered without biasing the primary objective—determination of clinical safety parameters.

Phase 2

After the initial introduction of a new drug into humans, Phase 2 studies are conducted. The focus of these Phase 2 studies is on efficacy, while the pharmacokinetic information obtained in Phase 1 studies is used to optimize the dosage regimen. Phase 2 studies are not as closely monitored as Phase 1 studies and are conducted in

patients. These studies are designed to obtain information on the efficacy and pharmacologic effects of the drug, in addition to the pharmacokinetics. Additional pharmacokinetic and pharmacologic information collected in Phase 2 studies may help to optimize the dose strength and regimen and may provide additional information on the drug's safety profile (e.g., determine potential drug–drug interactions).

Efficacy trials should not be initiated until the MTD has been defined. In addition, the availability of pharmacokinetic information in healthy volunteers is key to the design of successful efficacy trials. The clinical pharmacokineticist assists in the design and execution of these trials and analyzes the plasma drug concentration data upon completion of the efficacy studies.

During the planning stage of an efficacy trial, the focus is on the dosage regimen and its relationship to efficacy measurements. Plasma drug concentrations for various dosages can be simulated based upon the data collected in the first two studies in humans. The disease or physiological states of the test patients (e.g., organ dysfunction as a function of age), concurrent medications (e.g., enzyme inducers or inhibitors), and the safety data obtained earlier must be considered when choosing an optimal dosage regimen for the study. In addition, if the targeted site of the drug is in a tissue compartment, theoretical drug levels in this compartment can be simulated, which may help scientists determine the appropriate times for efficacy measurements.

On completion of the efficacy trial, a therapeutic window for plasma drug concentrations can be defined by reviewing the correlation between plasma drug concentrations and key safety and efficacy parameters. The goal is to improve efficacy and safety of the drug by individualizing the dosage based upon previous plasma drug concentration profiles in the same patient.

Phase 3

If the earlier clinical studies establish a drug's therapeutic, clinical pharmacologic, and toxicologic properties and if it is still considered to be a promising drug—Phase 3 clinical trials will be initiated. Phase 3 studies enroll many more patients and may be conducted both in a hospital or controlled setting and in general practice settings. The goals of Phase 3 studies are to confirm the therapeutic effect, establish dosage range and interval, and assess long-term safety and toxicity. Less common side effects and AEs that develop latently may be identified. In addition, studies targeted to evaluate and quantify specific effects of the drug, such as drowsiness or impaired coordination, are conducted during this phase.

Phase 3 studies are also used to identify the most appropriate population or subpopulation for the study drug and to establish a place for the drug in its therapeutic class. A drug may be developed in a therapeutic class that already has effective alternatives, but the investigative compound may have a better safety profile than its established competitors. A Phase 3 clinical study can be designed to assess relative safety profiles.

Closer inspection of drug interactions is warranted in Phase 3 clinical trials. In many disease states, the use of polytherapy is quite common, and the risk of drug–drug interactions is high, both from pharmacokinetic and pharmacodynamic perspectives. The likelihood of drug interactions and semiquantitative estimates of magnitude may be predicted from *in vitro* data (6). The potential for interactions needs to be evaluated from two perspectives: the potential that the new drug may affect the pharmacokinetics of other drugs, and the potential that other drugs may affect the pharmacokinetics of the new drug. The former generally depends on the ability of the new drug to affect various enzyme and carrier-mediated clearance processes. Most notably, this concerns the cytochrome P450 (CYP) isoforms but could also involve conjugative enzymes and transporters, such as p-glycoprotein. Drugs may be an effective inhibitor without being a substrate of a CYP isoform, as is the case for quinidine's inhibition of CYP2D6.

The potential for significant drug–drug interactions caused by other drugs requires knowledge of the components of clearance for the new drug and the likelihood that known inhibitors will be coadministered. For drugs with multiple pathways and a broad therapeutic index, the need for formal interaction studies may be limited. Population pharmacokinetic analyses of data obtained from Phase 3 studies may be used to help discover and quantify drug interactions due to classes of drugs often associated with inhibition (e.g., macrolides, systemic antifungals, calcium channel antagonists, fluoxetine, paroxetine) or induction (e.g., anticonvulsants, rifampin).

Most early clinical trials are conducted at university medical centers with physicians who specialize in a certain area of medicine. When study drugs are eventually marketed, however, general practitioners will be prescribing them as well. Therefore, it is important that family physicians are exposed to study drugs during this phase because they represent the segment of clinicians who will be writing most of the prescriptions. Similarly, to maximize the commercial return on drug development, a multi-indication strategy may be pursued (sometimes designated as Phase 5 if conducted postapproval). In addition, testing of the drug in foreign countries is

appropriate during Phase 3; however, other countries may operate under different regulatory obligations than in the United States.

Phase 4

Whereas Phase 1, 2, and 3 studies are conducted prospectively using subjects or patients whose entrance into the study depends on strict inclusion and exclusion criteria, Phase 4 studies employ mainly observational, rather than exclusionary, study designs. Postmarketing surveillance and any additional studies requested by the regulatory agency as conditional approval of the NDA are conducted during Phase 4.

Data collection in premarketing clinical trials is an extensive, scientific exercise. Detailed blood work, special laboratory tests, and careful physiologic monitoring are typical in these studies. Postmarketing studies, however, are often targeted for much larger patient populations (5000–10,000 or more), which limits extensive data collection from each patient and emphasizes collection of safety information. These studies are complemented by reports of AEs from patients not enrolled in a study. The large numbers of patients in Phase 4 studies make it easier for researchers to determine rare AEs and can help identify patient populations that are at particular risk for certain AEs. For example, demographic trends toward side effects involving geographic locus, gender, or race may be determined from postmarketing surveillance data.

PROTOCOL CONSIDERATIONS

The task of designing a clinical study cannot be undertaken until the study objective of that trial has been rigorously defined. The objective should explicitly state what is being investigated and vague language should be avoided (7). Once an unbiased and specific objective has been developed, scientists can build the study design around it and then develop and write the protocol (8).

One of the main considerations when designing an investigational study concerns the type and number of comparative groups that will be involved. A control group of subjects may be evaluated in addition to the group taking the investigational drug. Sometimes more than one control group is used in a study. The control groups take either placebo or active medication and are compared with the group taking the investigational drug. This design is used to rule out the possibility of a placebo effect or to assess the efficacy and safety of the investigational drug relative to other drugs currently marketed.

Regulatory agencies frequently require the pivotal Phase 3 studies, which will be used to support an NDA, to be placebo-controlled studies. Placebo medication should be as similar as possible to the drug being investigated (e.g., same color, taste, and shape). No statistically significant difference in response between this group and the subjects taking the investigational drug is evidence against that drug having any real effectiveness.

Similar to the placebo considerations, active medication taken by the control group also should be as similar as possible to the drug being investigated (e.g., same color, taste, and shape). If the formulations cannot be made with similar appearances (e.g., tablet, suspension, etc.), a placebo of each formulation could be made so subjects would take one active formulation and the placebo of the other formulation to maintain the blind. No statistically significant difference in response in this group relative to the subjects taking the investigational drug is evidence that active medication has no advantage therapeutically over the existing therapy. However, a higher incidence of AEs in the control group and an equal rate of efficacy relative to the subjects taking the investigational drug are evidence of the new drug's advantage over the existing therapy.

In addition to determining the types and number of control groups that should be included in a study, the drug development team must decide between a parallel and a crossover design. For example, in a placebo-controlled clinical trial, a parallel design is one in which each study group takes the same medication (i.e., either placebo or active drug) throughout the study. With a crossover design, each study group eventually receives both placebo and active drug (e.g., one group may take placebo for a 6-week period and then cross over to receive active drug for the following 6-week period).

An advantage of the crossover design is that it allows each group to be its own control, thereby allowing a demonstration of efficacy to occur during the treatment with the drug. A disadvantage of the crossover design is that residual effects from one treatment period may carry over into the other treatment period. Absolute determination of efficacy and safety of the different treatments is difficult and sometimes impossible. One way to avoid the problem of residual effects on crossover studies is to have washout periods between the different treatment phases. During the washout period, the patient is either given a placebo or no treatment for several days or weeks so that any possible metabolite or effect of the drug is "washed out" of the patient before the next treatment phase begins.

An advantage of the parallel design is that it avoids the problems associated with possible residual effects of one treatment period influencing the other treatment period(s) because each treatment group is only exposed to one drug.

Compared with a crossover study, more patients may be required for a parallel study so that statistical significance can be established between the study groups. In a parallel study, recruiting the required larger numbers of patients who fit the study criteria takes longer, but the duration of that study is usually shorter than the duration of a crossover study.

Crossover designs span greater periods of time because each group must sequentially take an active and a control medication over a period that is long enough to allow a treatment effect to emerge. When washout periods are added, the time required to conduct these studies becomes longer still, and more study subjects may drop out. These difficulties are often outweighed by the fact that statistical significance can be achieved with fewer patients in crossover studies.

Once the study design has been chosen, there are many other issues to consider when developing and writing clinical protocols. Among the topics to be considered are criteria for patient eligibility, efficacy and safety parameters, timing of the events, packaging and dispensing of the clinical trial material, and the informed consent form. Also, to be determined is how the study will be blinded. For most well-controlled studies, subjects are assigned to the various groups by using a randomization process so that biased selection is eliminated, the overall collection of the subjects' variables is comparable in each group, and statistical power is guaranteed (9). In these double-blind studies, neither the subject nor the investigating scientists know to which group the subject has been assigned. Thus, extensive input from the drug development team is required when designing studies and writing protocols.

DRUG DEVELOPMENT CONSIDERATIONS

Most drugs are tested in humans to treat a specific disease entity or some adverse clinical condition. Because the pathogenesis of diseases and the exact mechanisms of action of drugs are often poorly understood, the process of evaluating a drug's efficacy can be complicated. Upon treatment, a patient's adverse clinical condition may improve; however, for many diseases this occurrence can only be evaluated indirectly by clinical assessments (e.g., via blood pressure measurements in the treatment of hypertension). However, a drug's characteristics can also be measured directly. For example, measurement of blood concentrations of the drug enabling calculation of pharmacokinetic parameters is a direct evaluation of the drug.

Similar to efficacy assessments, evaluation of the safety of a drug may also involve indirect measurements. One of the primary methods of obtaining safety information in a

clinical trial is through a patient's reporting of AEs. Although the exact biochemical mechanisms responsible for many AEs cannot be evaluated directly, the indirect evaluation of the drug's adverse effect can be seen clinically. Because clinical assessments are indirect measures, AE reporting leads to several complex questions. The degree of drug-relatedness or causality, the effect of concomitant medication, the severity of the AE, the complications of the disease state, and the effects of other clinical conditions or diseases are usually difficult to determine, particularly early in the drug development program. Also, all reports of AEs in a clinical drug research program are recorded, tabulated, and cross-referenced to form a safety database, regardless of whether the AE is determined to be drug related. The information contained in this database is used to generate the package insert.

Although the clinical effect of a drug is perhaps the primary concern of drug development, an understanding of the drug's biochemical and physicochemical properties and mechanism of action is also desired. These direct measures are of equal concern in drug development as are the indirect evaluations of a drug's clinical effects. The primary tool used to study the intrinsic physicochemical properties of a drug is pharmacokinetics, which is a branch of biopharmaceutics. Pharmacokinetics describes the relationship between the processes of drug absorption, distribution, metabolism (biotransformation), and excretion (collectively abbreviated ADME) and the time course of therapeutic or adverse effects of drugs (10). Efficacy is determined by the drug concentration at the site of action, which generally is correlated with the drug concentration in the blood. The ultimate goal of pharmacokinetics is to characterize the sources of variability in the concentration–time profile, which may be correlated with variability in efficacy and adverse events.

Pharmacokinetics can be used to guide dosage regimen selection and thereby optimize pharmacologic effects and minimize toxicologic effects when a drug is administered to an individual patient. Thus, although the basic pharmacokinetic properties of a drug are identified during the earliest stage of clinical drug development, the many factors affecting the pharmacokinetics in the patient population must be identified throughout the drug development process to enable proper dose selection for individuals. Thus, both indirect and direct measures are used to evaluate a drug.

MARKETING INPUT

A successful pharmaceutical company has an appropriate blend of both research and marketing to enable a

symbiotic, rather than antagonistic, relationship. Because an effective scientific and clinical research team often designs and executes experiments and clinical trials that involve costly overhead expenses, it is essential for marketing decisions to be geared toward company profitability being made allow the company profitable so these expenses can be met. Therefore, both medical and marketing input are necessary if a pharmaceutical company is to be successful.

By gathering data on all facets of the needs in the marketplace from clinicians and by maintaining a profile awareness of new products under development by competitors, marketing personnel are in an excellent position to advise their colleagues in the research arena who are responsible for the drug development program. Also, a marketing expert can help identify the problems other companies are having in selling their product and thereby avoid the same difficulties. For instance, sales problems may be related to ineffective advertising or faulty packaging; therefore, they do not concern clinical research. However, problems in sales can also be related to a drug's undesirable effects. An effective drug that does not lead to the AEs associated with an already approved drug would have a marketing advantage. Someone in marketing research may suggest conducting clinical studies that would evaluate the relative incidence of the AE with the hope that the data could be used to support effective advertising.

Thus, research and marketing are mutually beneficial in a successful pharmaceutical company. Marketing groups help clinical research teams by supplying them with information about competing products, the needs of the marketplace, and suggestions for new formulations. Clinical research teams provide the data to support therapeutic and marketing claims and act as chief advisors to marketing personnel concerning drug research studies and promotional claims.

EFFECTIVE GLOBAL PLANNING

Because drugs are frequently marketed worldwide and the clinical development of drugs may involve studies that are conducted internationally effective global planning can present its own difficulties. Obviously, medical practice, regulatory guidelines, and the cultural environment may be different in various countries, but also the manner in which research is conceived can differ vastly between countries. Medical researchers in some countries may be more conservative than researchers in other countries, which could potentially lead to the underdosing of drugs.

These differences in research approaches actually stem from differences in ethical standards.

Another reason that international planning may be difficult in drug research concerns the way in which various countries view early clinical trials and drug safety. Some countries view volunteer subjects and patients differently from a regulatory perspective, making it easier to recruit and enroll subjects for Phase 1 studies than it is to recruit and enroll patients for Phase 2 or Phase 3 studies. In the United States, both patients and volunteers are viewed in the same way, and studies with patients and volunteers cannot be initiated until the FDA has authorized an IND.

In addition to regulatory guidelines, the regulatory process is still another aspect of clinical drug development that can differ widely between countries. In England, sponsoring research firms do not interact very much with the British drug regulatory agency the Committee on Safety of Medicines. This lack of direct interaction stems from the desire to keep commercial influence away from the objective evaluation of a pharmaceutical company's study data. This lack of communication results in British companies treating government guidelines for conducting clinical research as a routine checklist rather than an aid in forming the most appropriate development strategy.

In the United States, federal guidelines (Code of Federal Regulations, CFR) have been established by the FDA to help sponsoring research firms conduct good, consistent clinical studies. However, some of the items in these guidelines may not be appropriate for all clinical studies, and some items that may be appropriate to include in a clinical study may not have been incorporated into the federal guidelines. These variations occur because each drug and disease state is unique, and complete guidelines cannot be established for all cases. For these reasons, several meetings are held between clinical research teams and the FDA before an NDA submission to ensure that all appropriate methodology and experimentation is being incorporated into the overall drug development project.

Beginning in the early 1990s, the FDA participated in a collaborative effort to harmonize the technical procedures for development and regulatory approval of human pharmaceuticals internationally. Forces that led the agency in this direction included increased trade, the multinational nature of the pharmaceutical industry, trade agreements such as the North American Free Trade Agreement and the General Agreement on Tariffs and Trade by the World Trade Organization, European activism, and pressures on the industry to control costs (11). These pressures included intense competition and health care reimbursement controls. This harmonization effort is the work of the

International Conference on Harmonisation (ICH) of Technical Requirements for Registration of Pharmaceuticals for Human Use. ICH has focused on achieving harmonization of technical requirements in three major regions of the world: the United States, the European Union, and Japan. Some of the earliest ICH guidelines addressed the format and content of the Investigator's Brochure (12), stability testing (13), and genotoxicity testing (14). The FDA also works with the World Health Organization and other international organizations to set standards for health care products (11).

Clinical drug research is a complicated, multidisciplinary task that may be conducted internationally. In fact, many pharmaceutical companies are multinational, with locations in several countries. Planning and coordination become even more complex for such global drug development programs. Despite the differences among countries in medical practice, regulation, and culture, international drug development and marketing are vital parts of many organizations. The successful multinational pharmaceutical company will plan its clinical research strategy according to any differences among nations before to implementing its international development plans.

ETHICAL CONSIDERATIONS

No topic in clinical drug development is more controversial and emotionally charged than the myriad ethical dilemmas that face physicians and scientists involved in clinical research. Given that clinical research has generally proved to have moral consequences through its direct and indirect influence on alleviating suffering, steps must be taken to ensure that abuses do not occur during the course of drug development. Therefore, guidelines for the protection of human subjects have been developed, proposed, and accepted worldwide (15).

Because of the atrocities committed by Nazi medical researchers in the 1930s, the Nuremberg Code (16) was written, and highlighted the importance of obtaining all research subjects' voluntary consent to their participation in clinical studies. The Declaration of Helsinki (17), which was published by the World Medical Association in 1964 and has been updated several times since, takes the informed consent issue one step further by giving only qualified medical scientists and physicians the right to conduct clinical research. However, similar concerns go back at least to the 1830s, when Dr. William Beaumont developed a contract with a patient, and in the late 1800s, when a leprosy worker experimented on a patient without her consent (18).

Legislation that ensures the protection of human research subjects in the United States includes the 1979 publication of the Belmont Report on the Ethical Principles and Guidelines for the Protection of Human Subjects of Research (19). This report concerns the fine line between biomedical research and the routine practice of medicine and explores the criteria that determine the risk-benefit ratio in the consideration of conducting clinical research. It also addresses basic guidelines for the proper selection of human research subjects and further defines the elements of informed consent.

Other important legislation in the United States includes the FDA's Guidance for Institutional Review Boards (IRBs) (20) for further guarantees of protection for human research subjects. IRBs are independent committees that review proposed clinical research projects before the commencement of the research. These committees decide whether the risk to research subjects outweighs the potential benefit of the research; they can suggest modifications in the research proposal or disapprove the project altogether. IRBs must consist of both men and women of varying professions. At least one member must have his or her primary concern in a nonscientific area (e.g., a lawyer or clergyperson), and at least one member must not be affiliated with the institution at which the research will be conducted.

Closely related to the rights of human research subjects are the rights of routine patients involved in nonresearch medical matters. In 1973, the American Hospital Association published the Patient's Bill of Rights (21), which requires that the acting physician give his patients complete information concerning their diagnosis, treatment, and prognosis; that the patient be given respectful care; that the patient be given the opportunity to refuse treatment; and that the patient's records, condition, and medical care be treated confidentially.

Another ethical issue facing clinical research scientists concerns study design, in particular, the placebo-controlled clinical trial. The reason placebo-controlled clinical trials are conducted is quite compelling from a scientific standpoint: to ensure that the evidence supporting the efficacy of an experimental drug is actually due to the properties of the drug and not to the psychologic properties of the study subjects. In other words, if a placebo effect from the experimental drug occurs rather than a true therapeutic effect, then a comparison of the drug group with the placebo group will show statistically similar response rates. It is a way to help separate actual drug responses from placebo responses, especially in studies investigating psychiatric compounds, but also in other therapeutic areas with a clearer "physiologic" or "biochemical" basis.

One defense for conducting placebo-controlled clinical trials is that the subjects chosen for the placebo group are randomly chosen, so that no malicious withholding occurs. Also, many study protocols have provisions of study extension that guarantee subjects in placebo groups have the opportunity to take the drug as an extension of the study after they complete the original part, or they are offered the chance to receive alternative therapy. Study subjects may be given monetary compensation for their participation in studies, in addition to free, thorough physical exams, lab work, and physician visits.

Interestingly, experimental drugs have unknown side effects that can cause serious biochemical and physiologic problems, whereas placebo medication does not. This fact makes possible the contrary argument and objection, on purely ethical grounds, to giving study subjects experimental and hence unproven drugs. Of course, informed consent and careful monitoring by trained medical personnel help to alleviate the ethical problems associated with giving subjects an active, investigational drug. The most important aspect of all studies is that the patient be completely informed of all study procedures and agree to willingly participate in the study.

The most recent pressing ethical dilemma facing the clinical research scientist surrounds the increasing amount of research that is being conducted in biotechnical and genetic engineering. Ethical issues will continue to play important parts in the medical and legal worlds. Whereas pure science is value-neutral, its application is always open to debate. Undesirable extremes are likely to exist at both ends of the spectrum.

CONCLUSIONS

To conduct a clinical study for the evaluation of a new drug, a vast array of personnel is required. Physicians are largely used because of their knowledge of clinical medicine and patient care, whereas scientists are used because of their knowledge of the methodology and the science. Pharmacists serve a bridging function due to their unique training in therapeutics and the pharmaceutical sciences. Nonscientific personnel are indispensable because of their ability to coordinate the many facets of a drug development project.

The clinical evaluation of drugs involves many different levels of scrutiny before a drug product can be marketed. These levels include Phase 1 for safety testing, Phase 2 for evaluating efficacy and determining the correct therapeutic dose, Phase 3 for large-scale studies and determination of drug interactions, and Phase 4 for

postmarketing surveillance. Phase 1 studies are typically conducted in healthy volunteers, and Phase 2 through 4 studies are conducted in patients.

Study design plays a critical role in the clinical evaluation of drugs. A clinical study cannot be conducted without specifically outlined objectives and a definitive plan, which are vital components around which the study protocol is constructed. The use of placebo or active drug control groups in the study, and whether the design should be open, parallel, or crossover, must be determined. In most studies, patients are assigned to study groups randomly.

The developmental objectives facing the clinical research team include indirect evaluations of a drug's safety and efficacy, such as effects on vital signs or behavior, and direct evaluations of a drug's intrinsic properties, such as its pharmacokinetics and mode of action. Also, the marketing-medical liaison is important if research is to support future sales plans and advertising is to reflect study results. Finally, effective global planning is necessary because drugs are more frequently developed and marketed worldwide, and therefore involve differing patient populations and different government regulations. ICH guidelines have helped to standardize regulations worldwide.

The ethical dilemmas facing clinical research scientists affect much of the legislation that currently regulates the conduct of clinical trials. The goal of drug development research is to develop effective pharmacotherapy for mankind's ailments, and regulatory agencies have enacted legislation to prevent unethical research.

Although traditional medicines continue to be discovered and developed, the fields of biotechnology and gene therapy continue to advance. In addition, new methods to collect and evaluate clinical data on a real-time basis will help to speed the development process.

INTRODUCTION

Polymer coacervation is a long established, and widely used, method for reversible gelification and microencapsulation of biological materials such as liquid and solid drug compounds or cells. Coacervation is defined, by IUPAC, as the separation of colloidal systems into two liquid phases. It is to be distinguished from precipitation, which is observed in the form of coagulum or flocs and occurs in colloiddally unstable systems (1). The term coacervation was introduced in 1929 by Bungenberg de Jong and Kruyt, for a process in which aqueous colloidal solutions separate, upon alteration of the thermodynamic condition of state, into two liquid phases, one rich in colloid, i.e. the coacervate, and the other containing little colloid (2). Accounting for different phase separation mechanisms, coacervation was subdivided into simple and complex coacervation. In simple coacervation, the polymer is salted out by electrolytes, such as sodium sulfate, or desolvated by the addition of a water miscible nonsolvent such as ethanol, or by an increase or decrease in temperature. Conversely, complex coacervation is essentially driven by the attractive forces of oppositely charged polymers.

The earliest commercial application of coacervation was for the development of “carbonless” carbon copy paper by the National Cash Register Company in the late 1950s (3). More recently, the field of polymer coacervation has developed steadily so that a more refined and complete classification of coacervation systems can be proposed here (Table 1). Other classification schemes and related principles of coacervation for microencapsulation are available in the literature with illustrated examples (4–6).

In this contribution, we discuss coacervation as a phenomenon between one or two polymers in a solvent, although similar phenomena may occur with ionic or highly polarized forms of drugs such as between the anionic heparin and the cationic gentamicin or morphine (4), the anionic surfactants sodium cholate or sodium dodecylsulfate and cationic antidepressants (7), or anionic DNA and cationic forms of gelatin and chitosan in the presence of sulfate ions (8). Further, coacervation-like phenomena are increasingly used to engineer “smart” polymers that undergo reversible strong conformational and macroscopic changes upon small changes in the environment, e.g., pH, temperature, ionic strength (9). These polymers are essentially single or associated polyions designed for stimulus-responsive drug delivery, bioseparation, biomimetic actuators, or materials with switchable hydrophilic/hydrophobic surfaces.

According to the classification proposed in this paper (Table 1), polymer coacervation is generally observed in binary or ternary systems, in either aqueous or organic liquids. Three main mechanisms govern the process of coacervation in these systems: (i) Polymer desolvation, in binary and ternary systems, (ii) Polymer 2–Polymer 3 repulsion in a common solvent of the two dissimilar polymers, i.e., a ternary system; (iii) Poly(ion)–counterion interactions such as between poly(cation) and poly(anion) in a common solvent, i.e., a ternary system; similarly, a poly(H-donor)–poly(H-acceptor) interaction may also lead to polymer coacervation. Thus, polymer coacervation is a direct consequence of changes of molecular interactions operating between polymer–polymer (same species), polymer–solvent, polymer–coacervating agent, or poly(ion)–counterion. Prior to describing the various

Table 1 Classification of common aqueous and organic systems for polymer coacervation*Binary systems: Coacervation by partial polymer desolvation:*

Solvents (component 1) ^a	Water; Organic solvents
Polymers (P; component 2) ^a	Hydrophilic ^b P ⁰ , P ⁺ , P ⁻ ; Lipophilic P
Coacervation inducing factors	Temperature, pH

Ternary systems: Coacervation induced by partial polymer desolvation:

Solvents (component 1) ^a	Water; Organic solvents
Polymers (P; component 2) ^a	Hydrophilic ^b P ⁰ , P ⁺ , P ⁻ ; Lipophilic P
Coacervating agents (component 3) ^a	Nonsolvents for the polymer; Electrolytes ("Simple coacervation")

Ternary systems: Coacervation induced by Polymer 2–Polymer 3 repulsion:

Solvents (component 1) ^a	Water or organic solvent
Polymers (P2, component 2) ^a	Hydrophilic ^b P2 ⁰ , P2 ⁺ , P2 ⁻ ; Lipophilic P2
Coacervating agents (component 3) ^a	Polymer 3, P3

Ternary systems: Coacervation induced by noncovalent polymer cross-linking:

Solvents (component 1) ^a	Water ^c
Polymers (component 2) ^a	P ⁺ or P ⁻
Cross-linking agents (component 3) ^{a,d}	P ⁻ or P ⁺ ("Complex coacervation"); Di- and trivalent counter-cations or counter-anions

^aNumbering of components: 1-designates the solvent for the polymer to be coacervated; 2-designates the polymer to be coacervated; 3-designates the coacervating agent. The numbers are also used as subscripts in the equations.

^bP⁰, P⁺, P⁻ designate nonionic, cationic, and anionic polymers, respectively.

^cNonaqueous systems are not described in pharmaceutical technology.

^dP⁻ and P⁺ or the di- and trivalent counterions are integral components of the coacervate phase.

systems in more detail, it may be helpful to consider first some basic aspects of polymer solution behavior, knowledge that may be useful for understanding coacervation phenomena as well as for optimizing microencapsulation processes based on polymer phase separation.

Polymers dissolved in a solvent are encased in a sheath of solvent molecules that solvate their functional groups, typically through hydrogen-bonding and van der Waals forces. The envelope of solvation prevents chain segments in close proximity from attracting one another by interchain H-bonds, van der Waals or opposite ionic forces. Factors that lower the solvation of dissolved polymers thin out the sheath of solvation so that, at some point, contiguous chains attract one another by secondary valence bonds, thereby forming an entangled network or even noncovalent weak cross-links. Polymer chain desolvation is one type of mechanism leading to phase separation; under certain conditions, gelification rather than phase separation occurs. Factors that lower polymer solvation include temperature change, increase in molecular weight or, for poly(ions), pH-change in binary systems, or the increase in polymer concentration in binary or ternary systems. One very effective way to increase polymer solution concentration is to lower the number of solvent molecules available for polymer solvation. This can, be achieved practically, by adding a third component

to the polymer solution (ternary system) such as an electrolyte or a second liquid, which must be a nonsolvent for the polymer. The term nonsolvent is used here for all poor solvents for the polymer to be coacervated. The added electrolyte or nonsolvent will bind part of the polymer solvent. Competition for solvent of solvation will desolvate the polymer molecules leading to phase separation in the form of coacervates or precipitates. When electrolytes are used for polymer desolvation, the phenomenon is called salting-out. In aqueous systems, the effectiveness of dehydration, i.e., a particular form of desolvation, follows the so-called Hofmeister or lyotropic series, which arranges ions in the order of increasing salting-out capacity for hydrocolloids: $\text{NH}_4^+ < \text{K}^+ < \text{Na}^+ < \text{Ca}^{2+} < \text{Mg}^{2+}$ and $\text{Cl}^- < \text{acetate}^- < \text{SO}_4^{2-} < \text{tartrate}^{2-} < \text{HPO}_4^{2-} < \text{citrate}^{3-}$ (only pharmaceutically acceptable ions are indicated here).

When at least two dissimilar non-ionic, nonpolar, or only slightly polar polymers (Polymer 2 and Polymer 3) are mixed in a common solvent, phase separation generally occurs. This event is thermodynamically controlled and can be explained as follows (10). The dissolution of a polymer in a solvent is commonly endothermic (positive enthalpy of mixing, ΔH_m), thus counteracting dissolution. It is indeed the entropy increase (positive ΔS_m) that allows a polymer to dissolve in a

solvent, i.e., the entropy increases as the arrangement (or lattice) of the solvent molecules are largely disturbed by introducing long polymer chains, which require a relatively large molar volume inside the solution. When a second polymeric species (Polymer 3) is mixed with a solution of Polymer 2 in a common solvent, the two polymer species will typically interact through van der Waals forces, and this interaction is proportional to their molecular weights. This interaction would produce a substantial endothermic energy change whereas the entropy gain by this intermixing is very small owing to the small number of polymer molecules involved. Thus, because of the positive free energy change that would occur if the dissimilar polymers would mix with one another, phase separation into two distinct phases each of them rich in one of the two polymer species is thermodynamically more favorable.

Contrary to the aforementioned mechanism, pairs of oppositely charged poly(ions), or highly polarizable polymers, or of poly(H-donor) and poly(acceptor) tend to interact favorably with one another, i.e., their free interaction energy change is negative owing to a negative ΔH_m . Therefore, they may well coexist in a common solvent, or even attract one another so strongly that the negative ΔH_m dominates over the entropy gain in the common solvent. In this case, the two polymers will form a polymeric complex separating from the solvent. Depending on the strength of enthalpic interaction between the polymeric complex and the solvent, the complex may either precipitate as solid particles or remain partly solvated (complex coacervate). A comparable mechanism operates when a poly(ion) is mixed with a low molecular weight di- or trivalent counterion, such as Ca^{2+} , Mg^{2+} , Al^{3+} , Zn^{2+} , tartrate^{2-} . This type of mechanism leads to a strong non-covalent cross-linking of the polymer chains forming a relatively tight network.

Generally, all the mechanisms of polymer coacervation involve some sort of phase separation, thereby producing more or less dense coacervate microdroplets. These microdroplets can either engulf an additional component, such as a dissolved drug, or deposit on solid surfaces, which is typically used for coating solid particles added to the system, e.g., drug particles or living cells.

THERMODYNAMIC MODELS OF POLYMER SOLUBILITY AND PHASE SEPARATION

Fundamental aspects of coacervation have been thoroughly covered for some time through the classical

studies of Bungenberg de Jong and Kruyt for ionic systems (2), and by Dobry and Boyer-Kawenoki for non-ionic systems (11). The basic thermodynamic conditions for polymer-solvent interactions and polymer phase separation have been nicely described by Flory (10). In the following, polymer phase separation processes will be briefly considered from mechanistic and thermodynamic points of view.

Classical Models to Describe Coacervation Induced by Temperature Change and Nonsolvent Addition

In the early 1940s, Flory and Huggins proposed, separately, a lattice model to describe polymer solutions and introduced the interaction parameter χ (10). This parameter increases as solvent power decreases; hence, a thermodynamically good solvent is characterized by a low interaction parameter. In practice, most polymer-solvent combinations result in χ -values ranging from 0.2 to 0.6 (12). Moreover, the theory predicts that a polymer will dissolve in a solvent only if the interaction parameter is less than a critical value χ_c , which, at a given temperature, depends on the degree of polymerization (x) of the dissolved polymer (10):

$$\chi_c \approx \frac{1}{2} + \frac{1}{\sqrt{x}} \quad (1)$$

For polymers of very high molecular weight, χ_c approaches the value of 0.5. Upon gradual addition of a nonsolvent (with a large χ value), phase separation occurs in the order of decreasing x , i.e., when $\chi < \chi_c$. Further, χ also depends on temperature. This is generally illustrated by solubility phase diagrams, where single and two-phase systems are defined as a function of polymer volume fraction and temperature. The applicability of χ in coacervation is very limited, as χ is not a constant, but depends on polymer concentration, molecular weight, and temperature. Moreover, χ cannot be determined readily for polymer-liquid pairs and is inconvenient for multi-component systems. Finally, χ is a composite term influenced by hydrogen bonding.

More commonly used descriptors of polymer solubility are the solubility parameters introduced by Hildebrand and Scott (13) for dispersive interaction forces, and extended by Hansen (14) for dispersive (δ_d), polar (δ_p), and hydrogen bonding contributions (δ_h) to interaction energies. An equation sometimes used to estimate the solubility range of Polymer 2 in a solvent (subscript 1) is

$$\delta = [4(\delta_{d1} - \delta_{d2})^2 + (\delta_{p1} - \delta_{p2})^2 + (\delta_{h1} - \delta_{h2})^2]^{0.5} \quad (2)$$

According to Van Krevelen (15), $\Delta\delta$ should not exceed 5 MPa^{0.5} for good solubility. This rule of thumb may be applied to solutions with constant polymer concentration. However, the stepwise addition of a nonsolvent, followed by solvent partitioning between coacervate and continuous liquid, changes continuously the composition of a coacervation dispersion. Under the assumptions that the continuous phase consists exclusively of solvent and nonsolvent, and the coacervate phase of solvent and polymer, the solubility parameters of both phases may be calculated by

$$\delta_{\text{continuous phase}} = \phi_{1,\text{con}}\delta_{\text{solvent}} + \phi_3\delta_{\text{nonsolvent}} \quad (3)$$

$$\delta_{\text{coacervate phase}} = \phi_{1,\text{coa}}\delta_{\text{solvent}} + \phi_2\delta_{\text{Polymer 2}} \quad (4)$$

where $\phi_{1,\text{con}}$, $\phi_{1,\text{coa}}$, ϕ_2 , and ϕ_3 are the volume fractions of solvent in the continuous phase, of solvent in the coacervate phase, of polymer, and of nonsolvent, respectively. Although Equations 3 and 4 are empirical mixing equations with limited validity, they are frequently used in pharmaceutical technology to improve solvent mixtures for coating, film formation, and microencapsulation. The mean solubility parameter of the coacervation mixture can be calculated only for a single phase system, i.e., as long as the nonsolvent is soluble in the polymer solution. As solubility parameters of polymers cannot be determined directly from vaporization energy, various calculation methods have been proposed using the cohesive properties of functional groups and assuming additivity of these properties (16). Moreover, polymer solubility experiments in a variety of solvents of known solubility parameters, may be useful to define the borderline of good solvents and nonsolvents for polymer coacervation.

The Interaction Parameter χ to Describe Coacervation Induced by Polymer 2–Polymer 3 Repulsion

The theoretical treatment of polymer phase separation based on polymer-polymer repulsion requires an extension of the χ -parameter concept on two polymers in a common solvent. For this case, Scott (17) defined the critical conditions for phase separation, provided that the rather common conditions apply that $|\chi_{1,2} - \chi_{1,3}| \ll 1$ and $\sqrt{x_2} < \sqrt{x_3} < x_2 \dots$

$$(\chi_c)_{2,3} = 0.5 \left(\frac{1}{\sqrt{x_2}} + \frac{1}{\sqrt{x_3}} \right)^2 \left(\frac{1}{1 - \phi_1} \right) \quad (5)$$

where the subscripts 1, 2, and 3 refer to the solvent, the polymer to be coacervated (Polymer 2), and the second

polymer (Polymer 3; coacervating agent). If the Polymer 2 – Polymer 3 interaction parameter $\chi_{2,3}$ is approximated from solubility parameters (Eq. 6), estimated experimentally or calculated from group contributions

$$\chi \approx \frac{V_1}{RT} (\delta_2 - \delta_3)^2 \quad (6)$$

then, the critical volume fractions of the solvent (ϕ_1) and of both polymers (ϕ_2 , ϕ_3) can be calculated from

$$\frac{\phi_2}{1 - \phi_1} = \frac{\sqrt{x_2}}{\sqrt{x_2} + \sqrt{x_3}} \quad (7)$$

$$\frac{\phi_3}{1 - \phi_1} = \frac{\sqrt{x_3}}{\sqrt{x_2} + \sqrt{x_3}} \quad (8)$$

Unless the solubility parameters of both polymers are very similar, the polymers will be incompatible, leading to polymer phase separation, as $\chi_{2,3} > (\chi_c)_{2,3}$.

New Approaches to Characterize Polymer Coacervation

Another interesting approach to describe polymer coacervation is that of Van Oss (18), who defined the conditions for simple and complex coacervation by the interfacial interactions between similar and dissimilar molecules. In this model, the solubility, s , of the Polymer 2 in a solvent (subscript 1) depends on the free energy of interfacial interaction, ΔG_{212} :

$$RT \ln s = f(G_{212}^{\text{IF}}) \quad (9)$$

According to this equation, the solubility of the polymer molecules in a liquid will increase with increasing positive values of $\Delta G_{212}^{\text{IF}}$, as the polymer molecules will increasingly repel each other and thereby tend to disperse. If $\Delta G_{212}^{\text{IF}} < 0$, solubility decreases due to molecular attraction. In most pharmaceutical systems, molecular contributions to $\Delta G_{212}^{\text{IF}}$ will be from apolar Lifshitz-van der Waals ($\Delta G_{212}^{\text{LW}}$) forces and from Lewis acid/base ($\Delta G_{212}^{\text{AB}}$) forces. Hence, $\Delta G_{212}^{\text{IF}}$ is represented by

$$G_{212}^{\text{IF}} = -2 \left(\sqrt{\gamma_2^{\text{LW}}} - \sqrt{\gamma_1^{\text{LW}}} \right)^2 - 4 \left(\sqrt{\gamma_2^+ \gamma_2^-} + \sqrt{\gamma_1^+ \gamma_1^-} - \sqrt{\gamma_2^+ \gamma_1^-} - \sqrt{\gamma_2^- \gamma_1^+} \right) \quad (10)$$

where the second part of the right hand side describes the Lewis acid/base interactions. For a ternary system with two dissimilar Polymer 2 and Polymer 3 immersed in a solvent 1, $\Delta G_{212}^{\text{IF}}$ becomes

$$\begin{aligned}
G_{213}^{\text{IF}} = & \left(\sqrt{\gamma_2^{\text{LW}}} - \sqrt{\gamma_3^{\text{LW}}} \right)^2 - \left(\sqrt{\gamma_2^{\text{LW}}} - \sqrt{\gamma_1^{\text{LW}}} \right)^2 \\
& - \left(\sqrt{\gamma_3^{\text{LW}}} - \sqrt{\gamma_1^{\text{LW}}} \right)^2 \\
& + 2\sqrt{\gamma_1^+} \left(\sqrt{\gamma_2^-} + \sqrt{\gamma_3^-} - \sqrt{\gamma_1^+} \right) \\
& + 2\sqrt{\gamma_1^-} \left(\sqrt{\gamma_2^+} + \sqrt{\gamma_3^+} - \sqrt{\gamma_1^-} \right) \\
& - 2\sqrt{\gamma_2^+ \gamma_3^-} - \sqrt{\gamma_2^- \gamma_3^+}
\end{aligned} \quad (11)$$

For all exclusive Van der Waals interactions, the interfacial interaction energy between Polymer 2 and Polymer 3 immersed in a liquid reduces to

$$G_{213}^{\text{LW}} = \gamma_{23}^{\text{LW}} - \gamma_{21}^{\text{LW}} - \gamma_{31}^{\text{LW}} \quad (12)$$

which can be rewritten as

$$G_{213}^{\text{LW}} = \left(\sqrt{\gamma_2^{\text{LW}}} - \sqrt{\gamma_1^{\text{LW}}} \right) \left(\sqrt{\gamma_1^{\text{LW}}} - \sqrt{\gamma_3^{\text{LW}}} \right) \quad (13)$$

In coacervation processes induced by Polymer 2–Polymer 3 repulsion, the conditions for coacervation are, $\Delta G_{212}^{\text{IF}} > 0$. In apolar systems, this condition is fulfilled by $\gamma_2^{\text{LW}} > \gamma_1^{\text{LW}} > \gamma_3^{\text{LW}}$ or by $\gamma_2^{\text{LW}} < \gamma_1^{\text{LW}} < \gamma_3^{\text{LW}}$. In polar systems, however, coacervation becomes only predictable by solving Eq. 11. Contrary to simple coacervation, complex coacervation in a ternary system occurs only if the polymer molecules attract each other, and hence, the interfacial free energy becomes negative.

The apparent advantage of the Van Oss theory lies in the accessibility of the surface tension parameters. For a given solute, γ_2 can be determined from contact angle and Young's equation. Moreover, these parameters can also be derived theoretically from polymer group contributions as described by Van Krevelen (15). On the other side, it remains questionable if the Van Oss model is valid for systems where hydrogen bonding plays an important role, as interfacial tension measurements are unlikely to account for H-bonding forces.

POLYMER COACERVATION INDUCED BY PARTIAL POLYMER DESOLVATION (SIMPLE COACERVATION)

Process Description

Simple polymer coacervation is based on partial polymer desolvation in binary or ternary systems. This partial polymer desolvation may be induced by changing the temperature of the polymer solution, by adding to the polymer solution a poor solvent (or nonsolvent) for

the polymer, or by “salting-out” by electrolytes. The coacervate phase may form droplets in the stirred equilibrium phase or deposit as a film on a given solid or liquid surface, such as solid drug particles or droplets of aqueous drug solutions. In both situations, the coacervate can be stabilized by intermolecular physical or covalent cross-linking, which typically can be achieved by altering the pH or the temperature, or by adding a cross-linking agent (19). In pharmaceutical technology, simple coacervation, alike other coacervation types, is very frequently used to entrap drugs into microcapsules or micromatrices; the term microspheres will be used hereafter for both types of microparticles. If a drug should be entrapped in the coacervated polymer, a liquid or solid form of the drug is dissolved or dispersed in the polymer solution. Here, the principles of simple coacervation will be illustrated for two frequently used polymer types.

A very commonly employed simple coacervation procedure utilizes gelatin. Simple coacervation of gelatin typically involves the use of water-miscible nonsolvents for gelatin, such as alcohols, or salts, such as sodium sulfate. This produces a partial dehydration of the gelatin molecules at a temperature above the gelling point and leads to separation of a liquid gelatin-rich phase and an equilibrium liquid containing only minor amounts of gelatin. (Fig. 1). Finally, the coacervate droplets in the equilibrium liquid are hardened by physical or covalent cross-links (for example, by adjusting the pH to the isoelectric point or adding glutaraldehyde or formaldehyde).

A very frequently described family of polymers subjected to simple coacervation are cellulose derivatives, particularly ethyl cellulose (EC) (20). While most cellulose ethers are soluble in water, EC and the cellulose esters are insoluble or only partly soluble in water, e.g., as a function of pH. For coacervation of EC, toluene is a preferred good solvent and cyclohexane a poor solvent (21–23). Gradual addition of cyclohexane to a solution of EC desolvates the polymer. Alternatively, EC can be dissolved in hot cyclohexane; cooling to room temperature induces polymer phase separation. In both these cases, the coacervate film or droplets can be hardened by exposing the coacervate to a large volume of cyclohexane, whereby physical cross-links are formed.

Materials

Gelatin (24, 25) and cellulose derivatives (26, 27) are probably the most widely used polymers in simple coacervation for pharmaceutical purposes, although various other polymers have been successfully employed for the production of microcapsules by this process. In principle, any polymer can be utilized as a wall-forming material, provided that partial desolvation can be achieved.

Fig. 1 Schematic ternary diagram of a gelatin–water–alcohol system. The diagram shows the zone where two phases exist, i.e., the coacervate and equilibrium phases. The two-phase systems are represented by the area under the binodal curve (points A, B, C, D), whereas the area above the binodal represents single liquid phase systems of gelatin dissolved in water–alcohol mixtures. The arrow (points E, C, F) indicates the addition of alcohol into an aqueous solution of gelatin at an initial concentration of 20% gelatin. At approx. 18% alcohol (point C), phase separation occurs. At a given composition (point F), the two phases have the compositions denoted by the points D (equilibrium phase consisting of 40% alcohol, and 60% water) and B (coacervate phase consisting of approx. 46% gelatin, 15% alcohol and 39% water) situated at both sides of the so-called tie-line (dotted line). The ratio of coacervate to equilibrium phases, on a weight basis, is given by the ratio $D-F/F-B$.

The polymers subjected to simple coacervation include, amongst others, poly(styrene), poly(vinyl acetate), poly(vinyl chloride), poly(lactide) (5), poly(vinyl alcohol) (28), poly(acrylates) (29), chitosan/PVA-blends (30, 31), albumin (32), casein (33), and also vegetable proteins like vicilin (34), and legumin (35). For more detailed information, the reader is advised to consult the extensive reviews in this field (5, 6, 36, 37).

For simple coacervation induced by nonsolvent addition in aqueous systems, ethanol, acetone, dioxane, isopropanol, and propanol are the most preferred to cause polymer desolvation and phase separation. In organic systems, mainly nonpolar solvents, such as petroleum ether, cyclohexane, and paraffin, are useful.

Critical Process Steps and Product Characteristics

Simple coacervation involves four distinct steps: i) Phase separation upon polymer desolvation; ii) Droplet formation

or deposition of the coacervate phase on a given surface; iii) Hardening of the coacervate phase; and iv) Isolation of microparticles or surface-coated material. Coacervation is quite a complex physico-chemical phenomenon, and many factors affect the properties of the resulting product. Simple coacervation in organic and aqueous systems depends on molecular interactions of the materials involved at a given temperature, the presence of solid or liquid surfaces with a high affinity for the coacervate phase, the rate of polymer desolvation and fluid dynamic processes, e.g., diffusion, laminar or turbulent movements. Therefore, for any given system, the material and process parameters must be carefully studied to control fully the process. In general, simple coacervation is a relatively slow process where diffusion and partitioning of the components between separated phases may take a considerable length of time to reach equilibrium. Therefore, the process is commonly performed under non-equilibrium conditions. This makes the rate and duration of every process step very critical for obtaining reproducible products and preventing undesired coalescence or precipitation. All these difficulties, along with the need for sometimes large amounts of organic solvents and toxicologically critical cross-linking agents have probably hampered the introduction of this process into an industrial setting.

Applications

To our knowledge, simple coacervation has essentially remained a technology described by academics and used for research rather than in pharmaceutical industry. Green (38) first demonstrated the microencapsulation of oil droplets by simple coacervation of gelatin. In this study, gelatin coacervation was induced by sodium or ammonium sulfate. Since then, simple coacervation has been used to encapsulate foods, flavors, and pharmaceuticals (19).

Simple coacervation of cellulose derivatives has been used for microencapsulation of various drugs, such as theophylline (27), ibuprofen (39), indomethacin (26), adriamycin (40), and nicardipine (41). The goal of microencapsulating these drugs was to decrease their gastric irritation, mask the bitter taste and, very importantly, to achieve sustained release.

POLYMER COACERVATION INDUCED BY POLYMER 2–POLYMER 3 REPULSION IN TERNARY SYSTEMS

Process Description

In coacervation by Polymer 2–Polymer 3 repulsion, the addition of Polymer 3 causes phase separation between the

two polymer species dissolved in a common solvent 1. This phase separation produces a viscous, liquid phase of Polymer 2, i.e., the coacervate, and a low-viscous phase of Polymer 3, often called continuous or polymer-poor phase. Under stirring, coacervate droplets are formed and dispersed in the continuous phase. The solubility of Polymer 3 in solvent 1 should be superior to that of Polymer 2 in this common solvent. For particle production, the Polymer 3 should also function as stabilizer for the coacervate droplets to prevent their aggregation. Further, for the entrapment of a biologically active material, the coacervate must have a certain degree of fluidity and a high affinity to the core material, whereas the affinity between core material and continuous phase should be low (see below). Finally, the coacervate droplets still contain a substantial amount of solvent 1 and are, therefore, too soft to isolate. Hardening of the coacervate droplets by a hardening agent is required before the product can be collected as discrete microspheres or microcapsules. A typical experimental set-up for this coacervation process yielding polymeric particles is illustrated in Fig. 2.

Materials

Coacervation by Polymer 2–Polymer 3 repulsion has been applied to various polymers, although the biodegradable poly(lactide) (PLA) and poly(lactide-co-glycolides) (PLGA) have attracted the highest interest, particularly for drug microencapsulation and controlled drug delivery (42). PLA/PLGA are commonly dissolved in dichloromethane or ethyl acetate and coacervated by adding a second, relatively low molecular weight polymer such as silicone oil (poly(dimethyl siloxane), PDMS, 100–1000 mPas). For hardening the coacervate droplets, the coacervate mixture is transferred into a nonsolvent for Polymer 2, such as hexane, heptane, or low molecular weight cyclic siloxanes, e.g., octamethylcyclotetrasiloxane (OMCTS) or decamethylcyclopentasiloxane (DMCPS).

To a very limited extent, other polymers have been coacervated by this process to form microparticles, i.e., ethylcellulose, cellulose nitrate, poly(methyl methacrylate), cellulose acetate phthalate, poly(acrylonitrile-co-styrene), and poly(styrene) (4). For some of these, liquid poly(butadiene) (8–10 kDa) was employed as a coacervating agent.

The hardening of coacervate droplets may be accomplished either by subsequent desolvation and formation of van der Waals bonds or covalent cross-linking of the coacervated polymer (4). In the first process,

Fig. 2 Experimental set-up of a typical coacervation process by Polymer 2–Polymer 3 repulsion.

the coacervation mixture is transferred into a liquid which is a nonsolvent for Polymer 2, though it is a good solvent for Polymer 3. Examples of such hardening agents include hexane, heptane, very low molecular weight volatile siloxanes (OMCTS, DMCPS). In the chemical hardening process, a cross-linking agent, e.g., glutaraldehyde or diisocyanates, is added to the coacervate system. Typical functional groups on Polymer 2 that are useful for cross-linking reactions are hydroxyl, e.g., in cellulose ethers and esters, and amine groups.

Naturally, the aforementioned polymers may also be coacervated by desolvation upon adding a nonsolvent, such as hexane, heptane, liquid paraffin, or a vegetable oil. The advantage of using the coacervation by Polymer 2–Polymer 3 repulsion is that the viscosity and volume fraction of the coacervate phase and the stability of coacervated droplets can be controlled by the amount of added Polymer 3 (43). The control of these coacervate characteristics is important for preventing aggregation of coacervate droplets and for efficient microencapsulation of biologically active materials.

Critical Process Steps and Product Characteristics

The particular feature of coacervation by Polymer 2–Polymer 3 repulsion is that phase separation occurs already after the addition of a minute volume fraction of Polymer 3, which is in contrast to the coacervation by polymer desolvation (44). In the very first step, a dispersion of Polymer 3-in-Polymer 2 phase is formed (Fig. 3). Further Polymer 3 addition produces a phase inversion, whereupon the Polymer 2 phase (coacervate droplets) is dispersed in the Polymer 3 phase. Upon further Polymer 3 addition, the solvent is partially extracted from the coacervate droplets thereby increasing their viscosity and physical stability against coalescence. Optimal coacervate stability is generally achieved within a certain range of Polymer 3 volume fraction. This “stability window” has been determined by various authors for different PLA and PLGA types (43).

The main advantage of coacervation by Polymer 2–Polymer 3 repulsion over polymer desolvation resides in the good control of the composition and viscosity of both the coacervate and dispersing phases. This, in turn, provides a means to control particle size and prevent undesired coalescence of the coacervate droplets, as well as a way to enhance the wetting and engulfing of any biologically active material in either solid or liquid form. Indeed, encapsulation of core material requires primarily that the work of adhesion between core material and coacervate is substantially higher than that between core material and dispersing phase (44), which again depends on the respective composition of the two phases. Further, a certain degree of fluidity of the coacervate droplets will also increase qualitatively and quantitatively the encapsulation process.

Studies dedicated to drug microencapsulation by this type of coacervation method revealed that this method is quite suitable for the microencapsulation of peptide and protein drugs into PLA and PLGA in terms of

Fig. 3 Different stages of PLA coacervation by PLA–silicone oil (PDMS) repulsion in a ternary system using dichloromethane (DCM) as solvent: (a) Dispersion of PDMS in PLA/DCM; (b) Phase inversion yielding unstable droplets of PLA/DCM in PDMS; (c) Stable dispersion of well defined coacervate droplets; (d) Aggregation and precipitation of polymer particles upon exceeding PDMS-addition.

encapsulation efficiency. However, its drawback lies in the residual coacervating and hardening agents remaining in the microparticles that cannot be eliminated sufficiently and may hamper biomedical use. Therefore, efforts have been made to use coacervating and hardening agents that are relatively safe and to minimize the residues of processing liquids in the final product (45).

Applications

Coacervation by Polymer 2–Polymer 3 repulsion has been widely used in the field of drug microencapsulation into the biodegradable PLA and PLGA. (42) (see also the chapter on *Microsphere Technology and Applications* of this Encyclopedia). This type of microspheres is intended for parenteral administration and controlled delivery of low doses of very potent drugs. The microparticles produced by this method lie within a size range of 20–150 μm , depending on the process parameters, and can be injected by a conventional syringe and needle. To our knowledge, there is at least one PLGA-based microsphere product on the market for parenteral use that is produced by this particular method: Decapeptyl® Retard (Ferring AG, Kiel, Germany), which contains the LHRH-analog decapeptide triptorelin.

POLYMER COACERVATION UPON NONCOVALENT POLYMER CROSS-LINKING IN TERNARY SYSTEMS

Principles and Mechanisms

Complex coacervation in aqueous solution may be considered as a special case of network formation. Intermolecular forces such as Coulomb, van der Waals, hydrophobic, hydrogen bond, and dipole-charge transfer between polymers themselves, or polymers and low molar mass counterparts, cause phase separation, where the polymers are concentrated in a gel-like phase or a precipitate. The quality of the separated phases strongly depends on the chemical nature of the participating molecules and the separation conditions. The following combinations based on various dominating interactions have been reported:

1. Oppositely charged polyelectrolytes ("polysalt")
2. Highly polarizable polymers
3. H-donor/acceptor polymers
4. Polyelectrolytes/multivalent counterions

Fig. 4 illustrates the complex coacervation for systems 1 and 4. In system one, the complex is composed of two different polymer structures intermolecularly cross-linked (Fig. 4a), whereas in system 2, the complex is formed by the inter- and/or intramolecular bridging of a single polymer structure (Fig. 4b). Specific examples for the two complex types are sodium alginate (polyanion) with chitosan (polycation), and sodium alginate (polyanion)/calcium (divalent counterion), respectively.

From a kinetic point of view, the complex formation between a cationic and an anionic site is generally rapid, with rates in the order of fractions of seconds, though hours and days are occasionally required for the total

process (46). The rate-determining steps for complex formation are

- Diffusion processes for intermolecular contacts
- Rearrangements of the complex coacervate including both conformational changes and disentanglements.

In particular, these arrangements are relevant for polyelectrolyte components of low charge density, and/or polyelectrolyte components largely differing in molar mass, and concentrated systems (47).

The stoichiometry between polyelectrolytes has very often found to be 1:1 (48), though the optimal ratio of polyions can be as high as 20:1. Generally, as the polymer concentration decreases, the number of chains participating in the complex rises. Furthermore, the charge density required for coacervation is lower if the polymer-solvent interaction parameter (Flory-Huggins) is higher. Strong polyelectrolytes generally participate in 1:1 stoichiometries, though steric hindrance, for example via long pendant groups such as are typical in synthetic quaternary ammoniums, can disturb the so-called simplex ratio (49).

Macromolecular Characteristics for Effective Polymer-Polymer Coacervates

For both polymer-polymer complexation via ionic interactions and hydrogen bonding there is a critical chain length below which competitive binding is impossible (50). In general, polysalt formation is a function of various parameters including molar mass/chain length, charge density, chemical structure, type of the ionic group, and chain architecture. Interestingly, two polyelectrolytes of the same net charge can be complexed provided one is ampholytic, such as gelatin, and is polarized in the electric field of the other (51). In addition, medium conditions (pH, ionic strength, total concentration, temperature) influence the complex formation kinetics and complex properties.

Alginate-poly(L-lysine) and alginate-chitosan are, by far, the most common polymer-polymer coacervation systems, with the former often pregelled, in bead form, with divalent cations such as calcium or barium. As Table 2 indicates, polysaccharides with a rigid structure are generally favored for polysalt formation.

The polyanion-polycation combination generally involves one permanently charged polymer with a second whose charge density is pH-sensitive. Secondary interactions, principally hydrogen bonding, are usually required as is the flexibility of one of the chains (52).

For alginates, the copolymer composition (ratio of mannuronic to guluronic acid units) can influence the

ultimate complex properties. These include elasticity as well as permeability and mechanical resistance of coacervates cast into 2D or spherical membrane structures. The type of polymer-polymer coacervate (precipitate, sol, network) will also often be highly molar mass dependent, with useful membranes found within a narrow window. This often does not correspond to the molar mass range required for bioapplications, which is dictated by factors such as cell toxicity and biocompatibility.

Characterization

The most important applications of polymer-polymer coacervates involve the formation of semipermeable membranes. They represent ionically cross-linked polymer network structures and are generally permeable to water and low molar mass solutes, though they block macromolecules and proteins above a certain molar mass. Molar mass cut-off (MMCO) experiments are carried out, for example, via inverse-size exclusion chromatography. These nontrivial experiments (53) monitor the ingress of a synthetic probe or the egress of biomacromolecules. The complex steric and electrostatic interactions involved in passing through the tortuous pores imply that the apparent MMCO is dependent on the chemistry of the macrosolute. In particular, a higher cross-linking density results in a lower MMCO, though this is rigorously true only if the network is inert, which is frequently not the case (54). Furthermore, most polyelectrolyte complex gels require characterization via transport studies (kinetics) as well as equilibrium diffusion measures (thermodynamics).

Polymer-polymer coacervates, in microcapsule form, can be characterized by a number of methods, though the most accurate involves a compression-based

micromanipulated probe connected to a sensitive transducer (55). The precision of such techniques can be as high as 10%. Generally, a 1:1 stoichiometry provides the most stable microcapsules. Other properties, including the sphericity, transparency, or membrane homogeneity are also often characterized. Novel methods based on analytical ultracentrifugation are particularly useful for 2D membranes (56).

Applications

Table 3 lists some of the typical polymer-polymer coacervation systems investigated for microcapsule formation.

The system sodium cellulose sulfate/PDADMAC permits the encapsulation of sensitive biological materials by a simple one step procedure. The broad variety of encapsulation problems so far successfully solved by this system includes the encapsulation of biocatalysts (57, 58), hepatic microsomes for extracorporeal detoxification (59), cattle embryos (47), and various drugs for targeted or controlled-release delivery (60).

Polysalts have been prepared as microcapsules for enzyme entrapment (biocatalysts), in the separation of proteins (60) as well as in surfactant binding. Protein separation is particularly selective, with biomacromolecules separated according to their isoelectric point. Coacervation is the preferred method for water soluble drugs where no modification of the absorption kinetics are warranted.

Coacervation for Cell Encapsulation

Processing

Cell encapsulation by polymer-polymer coacervation is generally performed by extrusion of a polyanion solution, seeded with the cells of interest, into a collecting batch containing a cationic simple multivalent electrolyte and/or polyelectrolyte. As an alternative method, the emulsification of polymer-cell suspension in a vegetable oil followed by the internal gelation of the polyanion has been described (62). The latter results in more homogeneous gels. Cell microencapsulation is complex (63) and involves the following steps:

- Polymer sterilization (thermal; UV- or γ -radiation; chemical, e.g., ethylene oxide)
- Polymer depyrogenation to destroy or remove potentially toxic lipopolysaccharides
- Polymer dissolution, often in culture media, to a controlled solution viscosity
- Solution dilution under sterile conditions

Table 3 Typical polymer–polymer coacervates

Polyanion	Polycation	Reference
Alginate (sodium)	Poly(L-lysine)	(76)
	Chitosan	(77)

Gelatin	Acacia	(84)
	Arabic gum	(85)
	Chitosan	(86)

- Coacervation reaction control (polyion concentrations, contact time)
- Washing, required to remove nonreacted excess polymer
- Coating to reduce permeability and/or modify surface properties

Examples of cell encapsulation

Fig. 5 shows microencapsulated mice islets intended for intraportal (liver) transplantation to achieve clinical normoglycemia. The islet's β -cells produce insulin in response to a blood glucose stimulus providing a therapeutic alternative to daily insulin injections. The capsule size is optimized to permit oxygen diffusion (64) given an O_2 -diffusion distance of 0.2 mm in hydrogels. The specific chemistry permits the simultaneous control of permeability and mechanical properties. From extended studies it has been concluded that multicomponent polymer systems can offer advantages in comparison to binary systems (65), with the thick membrane acting as an entrapment zone and permitting the de-coupling of diffusive and mechanical characteristics.

The encapsulation of hepatocytes for a bioartificial liver, and cell therapy for the treatment of other hormone deficiencies or neurodegenerative diseases, such as Alzheimer's and Parkinson's, are also under investigation. Additional examples of cell encapsulation in polymer-polymer coacervates include non-autologous gene therapy (66), blood substitutes (67) as well as the treatment of prostate cancer (68). Pharmaceutical applications of microcapsules encompass, in addition, transdermal drug delivery and protein delivery such as is required in anti-inflammatory therapy for arthritis.

Scale-Up

While it is not the purpose of this chapter to produce an extensive list of technologies related to polyelectrolyte complexes, some unique examples warrant discussion. Shioya (69) has patented an encapsulation method that controls permeability, while Dautzenberg disclosed a general method, and family of materials, for polyelectrolyte complexation (70). Recently, Vorlop has developed a mechanical cutting method to divide a fluid stream and achieve throughputs as high as 10^4 kg/h (71). Other techniques useful for high volume applications include the rotating disk atomizer.

Applications in Analytics

Polymer-polymer complexation is generally detected via conductometric or potentiometric titrations. "Colloid titration" represents an inverse-system where a polymer with known characteristics, such as potassium poly(vinylalcohol-sulfate) or poly(diallyldimethylammoniumchloride), are used to quantify the concentration of polycation or polyanion, hence relying on a 1:1 stoichiometry (47). Using the cationic dye, toluidine blue, as an indicator, a metachromatic end point is detected. Both methods are volumetric.

INDUSTRIAL VIEW OF THE USEFULNESS OF COACERVATION AND RELATED PRODUCTS

Various microencapsulation techniques have been successfully applied for several years in industry, with a large number of patent applications filed to protect market

Fig. 5 Encapsulated mice islets in a 400 μm capsules made from sodium alginate/sodium cellulose sulfate/poly(methylene-co-guanidine) hydrochloride/ CaCl_2 .

shares and products, particularly in the area of contrast agents for diagnostic imaging, in agriculture, and in the food industry. In contrast to the many available consumer products based on encapsulation technology, only very few pharmaceuticals have succeeded in the market.

Primarily for safety reasons, manufacturing and marketing of pharmaceuticals is strongly controlled by regulatory guidelines, making product development and introduction especially challenging. Clearly, industrial large scale application of a technology such as coacervation primarily requires a sound and robust process and product design, which is the starting point of all full development work, but is also driven by other important criteria as outlined in Fig. 6. How do these basic considerations actually apply to products prepared by coacervation? To answer this question, the process of organic phase separation for preparing sustained release microspheres for parenteral administration is considered here as an example to illustrate the implications.

Key parameters for the quality of controlled release microspheres for parenteral use encompass the drug encapsulation efficiency, stability over time, syringeability, reproducibility of release kinetics, sterility, therapeutic efficacy, general safety, and local tolerability. Some of these aspects apply to the products made by all microencapsulation techniques, whereas others are mainly relevant to formulations prepared by coacervation. Furthermore for injection or aerosolizing, microspheres

require a compatible dispersant to wet the particles and keep them suspended for administration. The reconstitution vehicle will require developmental efforts as the surface properties of microspheres may be hydrophobic, especially when the particles have been prepared by coacervation and subsequent physical hardening in lipophilic hardening agent. From the authors' experience, insufficient attention is sometimes given to the development of the dispersant formulation, especially if

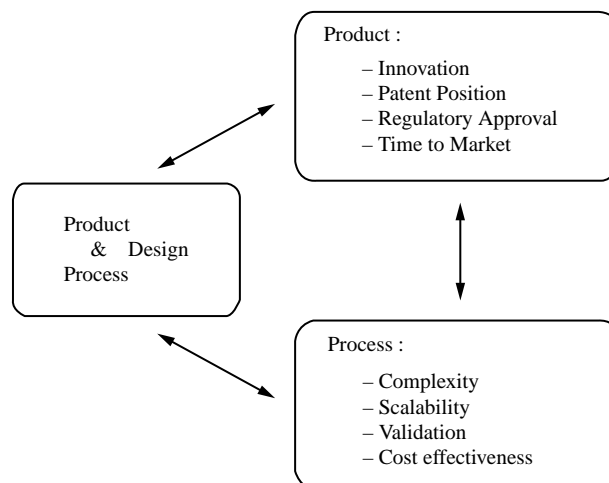

Fig. 6 Key elements for successful application of coacervation in the pharmaceutical industry.

active material and diluent are not manufactured at the same site.

Coacervation is a typical batch process requiring standard equipment with little need for costly investment, which contrasts to continuous microencapsulation processes such as aseptic spray-drying. For scalability, adequate and reproducible shear and stirring conditions, irrespective of the batch size, are very important. Selection of lab and pilot equipments suitable for scaling-up and featured with the necessary instruments to monitor critical parameters such as stirring and temperature are the basis for developmental work. Moreover, the introduction and dispersion of a given drug or bioactive material in the coacervation system also deserves particular attention. The particle size and dispersability of drug powder or drug solution are key parameters for high and consistent encapsulation efficiency and reproducible release kinetics. In organic phase separation, cleaning validation is a very challenging task, as coacervating and hardening agents require cleaning procedures with solvents and detergents suitable to remove efficaciously all coacervation components including non-entrapped drug or bioactive material. Because of this difficulty, the equipment of such critical processes are often product-dedicated to avoid any cross-contamination. In this respect, microencapsulation in aqueous systems is much easier to handle than in organic systems.

Nonetheless, organic phase separation remains an attractive method to encapsulate highly active, water soluble drugs such as peptides and proteins. The involvement of large quantities of organic solvents for production has, however, implications for the design of explosion-proof equipment and facilities. Further, residual solvents and hardening agents may hamper significant achievements for safety concerns. Efforts have therefore been devoted to replace the commonly used hydrocarbons or siloxanes by more biocompatible hardening agents such as isopropyl-myristate or propyleneglycol-octanoate/decanoate, which is used for the hardening of commercial PLGA microspheres containing triptoreline (Decapeptyl® Retard; Ferring). Evidently, such improvements are also relevant for patent protection (72, 73). Importantly, changes in processing solvents do not necessitate a new drug file application, but will be treated by the regulatory authorities as a postapproval change of an already approved process. Nowadays, where time to market is the key parameter for success, the choice of well characterized and widely accepted materials is of crucial importance. In this light, coacervation is a demanding technology because the number of useful and safe polymers, solvents and hardening agents is limited. Consequently, the quality, availability,

and cost of materials requires careful evaluation before decisions are made to introduce this technology in a pharmaceutical industry. Naturally, such a decision must also be driven by the therapeutic needs. Life saving indications, such as cancer treatment, may profit from a fast track approval by the authorities who balance carefully the pros and cons of possible formulation drawbacks and expected therapeutic benefit. Not surprisingly, microencapsulated parenteral depot formulations are found mainly in niche indications, where a limited and well controlled number of administrations in a relatively small group of patients is required.

Although coacervation is successfully used in pharmaceutical industry, the complexity of this and other microencapsulation technologies must not be underestimated, particularly in view of large scale manufacturing under aseptic conditions. Process design must consider this already at the developmental stage by keeping the number of individual manufacturing steps minimal. In this respect, sterile products prepared by organic phase separation require a significant number of unit operations:

- Sterile filtration/sterilization of excipients
- Mixing/dispersing and stirring
- Hardening by physical or chemical means
- Filtration
- Washing and sieving
- Dispensing and primary packaging (vials, syringes)
- Freeze-drying
- Terminal sterilization or full aseptic processing

For stability and safety reasons, full aseptic processing in a clean room environment is still the method of choice, although the intense involvement of personnel for a aseptic coacervation processing bears a substantial risk of contamination. By contrast, terminal sterilization by gamma or electron radiation provides a very high level of sterility assurance, but the efforts for validation and documentation of radiation sterilization are significant (74, 75). Moreover, radiation sterilization, although standard in the medical device industry, is not yet well accepted in all countries, a fact which again may hamper multinational filing and delay launch of a product.

In summary, the feasibility of coacervation has been shown on industrial scale, although it is probably fair to say that this technology is only scarcely used in pharmaceutical industry. Primarily for its physicochemical complexity and limitations with respect to residuals or processing components, efforts have been made to replace the coacervation technique by simpler technologies. To what extend new applications of coacervation technology in pharmaceutical industry will be successfully

commercialized will largely depend on the market needs and patient benefits of these new products, whereby the regulatory burden will play a major role. In this light, promising applications in the area of tissue engineering will definitely not be less challenging than those faced so far with the classical therapeutics.

CONCLUSIONS

Since the initial discovery of coacervation in the 1930s, a very large number of studies have dealt with coacervation, the underlying mechanisms, thermodynamics, materials, and applications. Nonetheless, relatively modest success and innovation in coacervation-based pharmaceutical systems have emerged. Clearly, the scientific achievements in this field, for example for the treatment of diabetes or the design of bioartificial organs, outweigh so far the commercial usefulness and benefit. Recently, however, coacervation has attracted great interest in the areas of DNA delivery from DNA-polymer complexes, in biotechnology, and in the food and agricultural fields. In the food sector, flavoring agents or agents with undesirable flavors, odors, acids, bases, artificial sweeteners, colorants, preservatives, leavening agents, among others, have been encapsulated by coacervation into materials such as starches, dextrans, alginates, proteins, and lipids. In the agricultural field, coacervation-based microencapsulation is used, e.g., for coating seeds. Finally, the ultimate relevance of coacervation may be in the biological existence and function of intracellular and extracellular complexes such as heparin-protein, DNA-protein, adrenergic agonists-protein. The association and dissociation of these complexes are very sensitive to pH, inorganic ions and electrical potential at membranes. These characteristics suit a plausible, though not elucidated process by which some pharmacological events may occur.

COLORING AGENTS FOR USE IN PHARMACEUTICALS

David R. Schoneker

Colorcon, West Point, Pennsylvania, U.S.A.

INTRODUCTION

The Need for Color in Pharmaceuticals

There is evidence that the coloring of pharmaceuticals has been practiced since antiquity, and although the use of colorants in medicinals produces no direct therapeutic benefit, the psychological effects of color have long been recognized.

The coloring of pharmaceutical dosage forms is extremely useful for identification during manufacturing and distribution. Many patients rely on color to recognize the prescribed drug and proper dosage. Unattractive medication can be made more acceptable to the patient by the careful selection of color. Color, in combination with flavoring agents, can be used to provide taste masking of disagreeable components of a pharmaceutical preparation. These attributes assist in improving patient compliance, which is known to be a significant problem when providing drug therapy for use in the home.

Additionally, recent reports defining the scope and magnitude of medical errors that have occurred are alarming. Although most of the medical error problems are related to practices by doctors and hospitals, some medical errors are related to mistakes made in identification of drug products by pharmacists and patients. Many drugs on the market look very similar (i.e., small, round, white, uncoated tablets) identified only by a small embossed or printed logo and identifier. This makes it very easy for a pharmacist or patient to confuse one drug for another. Obviously, this could prove to be very serious, depending on the drugs. The use of different colors for different drugs and strengths can help to eliminate this problem.

A number of pharmacy associations recently introduced a resolution at the 2000 USP Convention to develop standards for dosage form consistency that would include color, shape, size, labeling, and packaging. These types of standards would assist in developing new drug products with colors and other attributes that would make identification of the specific drug much easier. Although it would be very difficult to change the colors of existing drug products because of the amount of supporting information and regulatory review that would be needed, standards for future development might be beneficial.

History of Colorant Use in Foods, Drugs, and Cosmetics

Historical accounts describe many colors derived from animal, vegetable, or mineral sources that were used for coloring foods, drugs, and cosmetics. Until the middle of the nineteenth century, all colors were obtained from natural sources. Archaeologists date cosmetic colors as far back as 5000 BC. Ancient Egyptian writings tell of drug colorants, and historians say food colors likely emerged around 1500 BC.

The synthetic color industry dates back to the accidental discovery of the first synthetic organic dye (mauve) in 1856. Sir William Henry Perkin, in an unsuccessful attempt to synthesize quinine, succeeded in obtaining a violet dye by the oxidation of aniline. This led other scientists to experiment and discover many new colors with superior properties to the natural pigments and extracts. The use of these new and different colors in foods, drugs, and cosmetics began almost immediately because of their tinctorial value, stability, and the many shades in which they were available.

As the 1900s began, the bulk of chemically synthesized colors were derived from aniline, a petroleum product that in pure form is toxic. Originally, these were dubbed “coal-tar” colors because the starting materials were obtained from bituminous coal. Many of these colors are still used today, although with controls that ensure safe use.

Although colors from plant, animal, and mineral sources—at one time the only coloring agents available—remained in use early in this century, manufacturers had strong economic incentives to phase them out. Chemically synthesized colors simply were easier to produce, less expensive, and superior in coloring properties. Only small amounts were needed. They blended nicely and didn’t impart unwanted flavors to foods and drugs. But as their use grew, so did safety concerns.

Early uses of synthetic colors were at times a threat to health because they were used without discrimination between those that were toxic and those that were safe. Increasing public concern around the world led to early studies and regulations that produced various lists of colors found suitable for addition to foods and drugs.

The United States was one of the first countries to significantly regulate food and color additives because of a

number of incidents that occurred related to the safety of these materials. In 1906, the U.S. Congress passed the Pure Food and Drug Act. This marked the first of several laws allowing the federal government to scrutinize and control additives use. The act, however, only covered food coloring.

The Pure Food and Drug Act of 1906 listed seven colors, based on the work of Dr. Bernhard Hesse, and the Department of Agriculture made provisions for certification of all food colors on a voluntary basis.

It was not until passage of the Federal Food, Drug, and Cosmetic (FD&C) Act of 1938 that the Food and Drug Administration's (FDA's) mandate included the full range of color designations consumers still can read on product packages: "FD&C" (permitted in foods, drugs and cosmetics), "D&C" (for use in drugs and cosmetics), and "Ext. D&C" (colors for externally applied drugs and cosmetics). The 1938 FD&C Act also made certification mandatory.

Public hearings and regulations that occurred after the 1938 law gave colors the numbers that separate their hues. These letter and number combinations—FD&C blue #1 or D&C red #17, for example—make it easy to distinguish colors used in foods, drugs, or cosmetics from dyes made for textiles and other uses. Only FDA certified color additives can carry these special designations.

The law also created a listing of color "lakes." These water-insoluble forms of certain approved colors are used in coated tablets, cookie fillings, candies, and other products in which color bleeding could affect product quality or otherwise cause problems.

Although the 1938 law did much to bring color use under strict control, nagging questions lingered about tolerance levels for color additives. One incident in the 1950s, in which scores of children contracted diarrhea from Halloween candy and popcorn colored with large amounts of FD&C orange #1, led the FDA to retest food colors. As a result, in 1960, the 1938 law was amended to broaden the FDA's scope and to allow the agency to set limits on how much color could be safely added to food, drug, and cosmetic products.

The FDA also instituted a premarketing approval process that requires color producers to ensure, before marketing, that products are safe and properly labeled. Should safety questions arise later, colors can be reexamined. The 1960 measures put color additives already on the market into a "provisional" listing. This allowed continued use of the colors pending the FDA's conclusions on safety.

From the original 1960 catalog of about 200 provisionally listed colors, which included straight colors and lakes, only lakes of some colors remain on the

provisional list. Industry withdrew or the FDA banned many, while the rest became permanently listed and are still used. Some of these colors, derived from coal or petroleum sources, are subject to certification and carry the F, D, or C prefixes. Others, exempt from certification, are pigments and colors derived from plant, animal, and mineral sources. They are found in a myriad of food, drug, and cosmetic products.

Similar initiatives developed in most industrialized countries and regulations were implemented to control the use of color additives for use in foods and drugs. Although in most countries, food and drug colorants are strictly regulated, this is not the case in some regions in the Third World. Additionally, in some countries, cosmetic colorants are less regulated than the food and drug colorants. When using colorants from Third World countries, it is important to carefully assess the quality of these materials to ensure that they meet the requirements for the countries where the product will be marketed.

Worldwide Regulatory Considerations

Safety assessment

Ongoing toxicology studies are routinely being conducted worldwide by organizations such as the World Health Organization (WHO), the U.S. FDA, and the European Commission (EC) to assess the safety in various applications. Many articles have been written on assessing the safety of food colorants (1–6). Scientific and public opinion vary on the true interpretation of safety, and these views have impacted the development of food and drug regulations around the world.

Although these colors have a good safety record, consumers have voiced certain concerns about hyperactivity and allergic sensitivity regarding some of the synthetic colors.

Although this theory was popularized in the 1970s, well-controlled studies conducted since then have produced no evidence that food and drug color additives such as azo dyes (FD&C yellow #5, FD&C yellow #6, etc.) cause hyperactivity or learning disabilities in children. A Consensus Development Panel of the National Institutes of Health concluded in 1982 that there was no scientific evidence to support the claim that colorings or other food additives cause hyperactivity. The panel said that elimination diets should not be used universally to treat childhood hyperactivity, because there is no scientific evidence to predict which children may benefit. The FDA's Advisory Committee on Hypersensitivity to Food Constituents concluded in 1986 that FD&C yellow #5 (tartrazine) might cause hives in fewer than 1 out of 10,000

people. The Committee found that there was no evidence the color additive in foods provokes asthma attacks or that aspirin-intolerant individuals may have a cross-sensitivity to the color. As with other color additives certifiable for food and drug use, whenever FD&C yellow #5 is added to a food or drug, it is listed on the product label. This allows the small portion of people who may be sensitive to the color to avoid it.

During the early 1980s, before some of these reports were available, a regulation was included in Title 21 of the Code of Federal Regulation (CFR) regarding additional label requirements for FD&C yellow #5 concerning allergenicity. This regulation (201.20) required that for prescription drugs only, in addition to the label declaration showing that the product contains FD&C yellow #5, the label must also bear this warning statement: "This product contains FD&C yellow #5 (tartrazine) that may cause allergic-type reactions (including bronchial asthma) in certain susceptible persons. Although the overall incidence of FD&C yellow #5 (tartrazine) sensitivity in the general population is low, it is frequently seen in patients who also have aspirin hypersensitivity" (7).

When considering the very small potential for this type of a reaction, when compared with other products on the market with higher allergenic potential, and the conclusions of the FDA's Advisory Committee on Hypersensitivity to Food Constituents and the Consensus Development Panel of the National Institutes of Health, it appears that this statement may be overly cautious. However, this statement is still required for prescription drugs based on current U.S. regulations.

No similar type of warning statement is required for nonprescription drugs or foods. In reality, the potential exposure to FD&C yellow #5 is much greater from these products than from prescription drugs. Therefore, this regulation does not seem to make sense, given the current information. Although the industry has requested that this regulation be eliminated, the FDA has not taken any action on this as of this time. This has created much confusion concerning the actual data regarding hypersensitivity and allergenicity of FD&C yellow #5. Because of this confusion in the marketplace, most pharmaceutical companies have eliminated the use of this colorant in their prescription drug formulations to prevent the need for this misleading label requirement, which could create consumer concern.

To complicate matters more, there is also a European requirement being instituted to place allergen labeling on drug labels for a number of synthetic colors. Sound scientific data showing a need for this labeling is not apparent, and this requirement seems to be based more on nonscientific consumer concerns than on any real need. Considering the lack of evidence that FD&C yellow #5

(tartrazine) and other azo dyes such as FD&C yellow #6 (Sunset yellow FCF) cause any significant hypersensitivity or allergenicity problems, except in very rare cases, it appears that all that should be necessary is to make sure that the colorants are listed as a component on drug labels. These types of label requirements already apply in most industrialized countries and provide appropriate controls to allow those few people who are affected by these colors to manage their intake.

Nonharmonized regulations

Government regulations concerning the use of color additives change frequently, thereby making it difficult to be complete and accurate in listing colorants for use in international pharmaceutical development.

Legislation in various countries differs significantly regarding the color additives and their uses, although the principles of the laws are similar. These differences have led to certain colors being acceptable in one country and not being permitted in another. This creates a significant challenge to a pharmaceutical formulator when selecting colorants for use in global drug development.

In addition to assessing whether a particular colorant is approved for a specific use in certain countries, it is important to note that the specifications that each colorant must meet may also vary significantly from one region to another.

For instance, iron oxides are well known for being some of the most globally accepted colors. They are approved for use in drugs in most countries in the world. However, there are significant differences in the specifications for the various iron oxides listed in U.S. European, and Japanese regulations which mean that only certain iron oxides available in the marketplace can meet all of these requirements. In most cases, these grades must be subjected to many tests to provide assurance of compliance, which impacts the costs of these grades.

If a formulator is not extremely cautious in selecting an appropriate grade, the finished dosage form made from that grade may only be able to be marketed in certain countries, but not others. This would potentially mean development of multiple versions of the drug if the manufacturer determines that they would like to market the product in these other countries later on. The costs of this type of development can be very high and could potentially be eliminated by carefully selecting grades of colorants during early development of the drug that meet all of the requirements of the target market envisioned by the manufacturer. Of course, this requires that the pharmaceutical manufacturer identifies all the anticipated target markets for a particular drug product up front. Historically, many companies have not done this

until after the drug product has undergone many studies and, potentially, even regulatory reviews. Changing the colorant at this stage is very difficult.

Another interesting example that further illustrates this issue is the differences in regulations concerning D&C yellow #10 and Quinoline yellow between the United States and Europe. Although the Color Index (CI) numbers are the same, the dyes differ in composition as defined in the regulations. Quinoline yellow's purity criteria is defined in European Directive 94/45/EC as E104, which requires that the material contain not <80% of the disulfonated component of the dye and not >15% of the monosulfonated component (8). D&C yellow #10 is listed in the U.S. 21CFR (74.1710) which requires that the dye contain not <75% of the monosulfonated component and not >15% of the disulfonated component of the dye (9).

These specifications are mutually exclusive meaning that if a formulator desires the color obtained from these colorants, two versions of the drug product will be required if the product is to be marketed in both the United States and Europe.

Neither version of this dye is currently approved in Japan for use in drugs because of a lack of precedent. It would probably be possible to obtain approval in Japan if a manufacturer included one of these colorants in a new drug application and provided adequate safety data to convince Japanese regulators that the colorant is safe. However, in practice, most companies avoid using colorants that lack a precedent of previous use in Japan because this will usually delay drug approval.

Additional U.S. regulatory requirements— FDA certification

All colorants intended for use in the United States are regulated by the FDA as specified in the FD&C Act of 1938 and the 1960 Color Additives Amendment. The latter legislation defines a color additive as "any dye, pigment, or other substance made by a process of synthesis or similar artifice, or extracted, isolated, or otherwise derived, with or without intermediate or final change of identity, from a vegetable, animal, mineral or other source and that, when added or applied to a food, drug, or cosmetic or to the human body or any part thereof, is capable (alone or through reaction with another substance) of imparting a color thereto"(10).

The 1960 Color Additives Amendment also listed those color additives that need to be certified and those that are exempt from certification. The law establishes that color additives can be used under provisional listings until scientific investigations determine that they are suitable for permanent listing. See Tables 1 and 2 for a listing of permanently and provisionally listed colorants (11).

The certification procedure requires manufacturers of certified colorants to submit a sample of each batch of the color to the FDA for chemical analysis. If the results of the analysis comply with the specifications in the CFR, a certification lot number is assigned, and a certificate is issued for that batch. No color that requires certification can legally be used in the United States without being previously certified by the FDA. The certification lot number should be referenced in all documentation regarding the use of these colorants.

This procedure allows the FDA to be certain that all batches produced of a given color are chemically similar to the batches used in the original toxicology studies that were the basis for colorant approval.

TYPES OF COLORANTS APPROVED IN VARIOUS REGIONS

U.S. Certified Synthetic Colorants

The FD&C Act divided the synthetic colors into three categories: colors for foods, drugs, and cosmetics (FD&C), colors for drugs and cosmetics (D&C), and colors for externally applied drugs and cosmetics (external D&C). All synthetic colorants approved for use today must meet the specifications, uses, and restrictions as described in Title 21 of the CFR (Parts 74, 81, and 82). Certified synthetic colorants are the primary source of colorants used in the pharmaceutical industry.

FD&C colorants

The present list of FD&C certified colorants consists of both dyes and lakes. Lakes are pigments. They are insoluble materials that color by dispersion and reflected light. FD&C dyes are water-soluble and exhibit their color by transmitted light.

FD&C dyes: Today, FD&C dyes are synthetic organic molecules produced from highly purified intermediates derived from petrochemicals and other sources. The stigma of the association of FD&C dyes with coal tar no longer exists because of these starting materials. They are marketed in a number of physical forms, such as powder, granular, pastes, liquids, and dispersions. Many of these forms are customized for specific uses and are selected by the user for their particular application.

Dyes are relatively unstable because of their chemical structures. They are subject to instability as a result of: 1) light energy, 2) oxidizing and reducing agents, 3) microorganisms, 4) trace metals, 5) pH, and 6) high temperatures.

^aBased on 21 CFR 2000. Restrictions may exist limiting the use of some of these colors to specific applications (i.e., external drug use only, etc.). Additionally, there may be quantitative limits for the use of some colors. The specific 21 CFR reference for each color should be reviewed to determine potential restriction status.

The instability to these parameters and the solubility limits differ from color to color and should be considered when selecting dyes for use in various applications.

FD&C lakes: The only lakes permitted for use in all three categories—foods, drugs, and cosmetics—are the aluminum lakes. These are manufactured through the adsorption of an aluminum salt of an FD&C dye on a base of alumina hydrate.

The properties of these lakes can be controlled by variations in process conditions during manufacturing (for example, starting materials, order of additions, pH, and temperature). The most important attributes of aluminum lakes are the shade and particle size. The shade of the lake may be influenced by the quantity of dye adsorbed onto the alumina hydrate and the particle size distribution. The particle size also affects the tinting strength (that is, coloring power) of the pigment. Smaller particles result in increased surface area, which allows for an increase in reflected light and hence more color.

For additional information on the chemistry and properties of certified colors see Ref. (12).

D&C and external D&C colorants:

D&C and external D&C colorants may be used to color drugs and cosmetics with certain restrictions. A basic regulatory difference between FD&C, D&C, and external D&C colorants is that D&C and external D&C colorants have specific uses and restrictions. The classifications of D&C and external D&C mean little today, because many of the colorants listed as D&C are restricted to external uses.

D&C and external D&C colorants may also exist in either the dye or lake form; however, the majority of the commercially significant D&C and external D&C colorants are lakes.

D&C and external D&C dyes: The starting materials used in the manufacture of this class of colors are similar to those used for FD&C colors. D&C and external D&C dyes may or may not be soluble in water. Some are insoluble metal salts, and others are insoluble because they contain no water solubilizing groups. Several, however, are soluble in organic solvents.

Analogous stability problems exist between D&C, external D&C, and FD&C dyes, although there are a few D&C colors that are considerably more stable than the FD&C colorants.

D&C and external D&C lakes: These lakes are usually manufactured by precipitating a soluble dye onto an approved substrate. In the case of D&C colors, the substrate may be alumina, blanc fixe, gloss white, titanium dioxide, zinc oxide, talc, rosin, aluminum benzoate, calcium carbonate, or any combination of these materials.

A notable difference between FD&C and D&C lakes is that FD&C lakes must be manufactured using previously certified dyes, whereas D&C lakes are not restricted by this requirement. However, the regulations may change in the future requiring all lakes to be made from previously certified color.

The lakes made from D&C dyes are subject to the same uses and restrictions as the color from which they are derived.

The important physical properties of the FD&C lakes, such as particle size and shade, are equally important characteristics of the D&C and external D&C lakes.

Colorants Exempt from U.S. Certification

Certain colorants are not required by the FD&C Act to be certified by the FDA before use (Table 3). These include natural organic and inorganic colorants and certain synthetically produced so-called, nature-identical colors such as β -carotene. Although these colors are exempt from certification, they are still regulated by the FDA regarding their specifications, uses, and restrictions.

Most colors exempt from certification are obtained from animal, vegetable, or mineral sources. Most of the inorganic pigments are synthetically produced. Some examples would be titanium dioxide, synthetic iron oxide, and zinc oxide.

The inorganic colorants generally have good stability in a variety of applications. They tend to be less sensitive to heat and light than most of the other types of colorants used in pharmaceutical products. Titanium dioxide is a widely used white pigment. The other inorganic pigments are mainly earth tones.

Many of the natural organic colors in this category are extracts of a specific plant or insect. These extracts are then processed into a usable form. Because of the different sources of these materials, the properties vary greatly for each colorant and also exhibit batch-to-batch variation. Because of the types of raw materials used and the difficulties in manufacturing, these materials tend to be very costly.

Most of the natural organic colorants exhibit poor stability. They are very sensitive to heat, light, and environment. At present, their use is limited because of difficulties in incorporating them into specific products. In general, they exhibit far less tinting strength and lack the range of colors and color reproducibility that can be obtained when using synthetic colorants. In some cases, they may also flavor the product being colored.

Many schemes have been contrived to improve the stability of the natural organic colors. There are also many novel approaches for incorporating these colors into

Turmeric	E100	75300	Curcumin

Note: Aluminum lakes prepared from colors mentioned in this list are also authorized.

^aThese colors are approved for specific types of drug use based on an EU legal opinion that cross-references the list of approved drug colors to those listed in EC Directive 94/36/EC that regulates food colors (15). Restrictions may apply to some of the colors concerning the types of applications where they can be used and the maximum amounts which can be present. A new EC Directive, which specifically covers drug colors, is expected in the future to help clarify the situation.

^bSome colors and their derivatives share the same EEC Number. The number and lowercase letter identify the derivatives.

^cThese colors are currently listed for use in previously approved drugs. However, these colors should be avoided in new drug applications.

^dThis is not D&C yellow #10. Although the C.I. numbers are the same, the dyes differ in composition. Quinoline Yellow is primarily the disulfonated quinoline dye, whereas D&C Yellow #10 is the monosulfonated color. Quinoline Yellow is not accepted for use in the U. S.; conversely, D&C yellow #10 cannot be used in the EU.

Table 5 Approved drug colorants for use in Canada in 2000^a

^aBased on the Canadian Department of Health's Food and Drug Regulations on Coloring Agents; Part C.01.040.2; Aug 30, 1995 (16).

products and processes. However, they have met with little success. Although the use of natural organic colors may be desired for a number of reasons, in a majority of these cases it proves impractical.

Much research is currently underway to support the use of additional colors exempt from certification. Color Additive Petitions are being submitted and reviewed by the FDA for a number of new colors and extended uses of existing colors. During the next several years, it is expected that many of these colorants may be approved for these uses in the U.S. pharmaceutical industry.

Major Colorants Used in Multinational Pharmaceutical Applications

As mentioned earlier, when using colorants in pharmaceutical products to be produced or marketed in countries other than the United States, it is extremely important that the target market be established during the product development stage, because the colorant regulations vary significantly from country to country. Various official references are available that can be used to assess the regulations and requirements regarding approved colorants in specific countries (4, 5, 11, 5, 13–17). Additionally, some color usage guides are available from several color manufacturers, which can be helpful.

Most European countries follow the European Directives that list the colorants and specifications for use in foods and drugs in the European Union (EU). The directive that has previously controlled the approved colorants for

use in pharmaceuticals in Europe is 78/25/EEC, which refers to a list of colorants from a 1962 directive (13, 14). The EC published European Directive 94/36/EC in 1994, which significantly changed the list of approved colorants for use in foods. For example, Allura red AC (FD&C red #40) and Brilliant blue FCF (FD&C blue #1) were now approved for use in foods, however, these materials did not exist on the list of approved drug colorants because of the cross-referencing of the pharmaceutical directives back to the 1962 list. This has created much confusion throughout industry and the regulatory community.

Recent discussions within the EU have indicated that the colorant list from 94/36/EC will be rationalized into a new pharmaceutical color directive in the future so that the colorant lists will be aligned. It is now considered acceptable to use these colors in new drug applications even though the formal directives have not yet been finalized. However, each country may have some specific regulations for the use of these colorants in pharmaceuticals that must also be considered. Some nonmember European countries, such as some Scandinavian countries, severely restrict the use of synthetic colors and in some cases oppose their use entirely.

The purity criteria specifications for colorants approved for use in Europe are laid down in European Directive 95/45/EC (8). Each colorant defined by an EEC number has a monograph listing the required tests and limits. The regulation does not specify the test methods to be used for these tests; however, the Joint Expert Committee on Food Additives (JECFA) methods are generally acceptable. Any

^aBased on colors approved by the MHW's "Ministerial Ordinance to establish Tar colors which can be used in Pharmaceuticals"; No. 30; August 31, 1966. Aluminum lakes of these colors are also authorized.

^bNot more than 0.1% by weight of color (lake or dye) can be used in a dosage form (BIRYO limit on trace amounts).

Note: ^{d, e, f, g, h, i, and j}—Precedent limit listed in the Japanese Pharmaceutical Excipients Directory (JPED) 2000, Japanese Version (18). This limit represents the maximum daily dosage that a patient should consume from the use of a particular dosage form.

^cColor is permitted but use is generally discouraged for new drug applications.

^dNot more than 1.8 mg/day.

^eNot more than 95.4 mg/day.

^fNot more than 5.67 mg/day.

^gNot more than 1.539 mg/day.

^hNot more than 0.4 mg/day.

ⁱNot more than 2.0 mg/day.

^jNot more than 75 mg/day.

^kMust comply with Medicinal Carbon JP specifications if used for manufacture in Japan.

colorant that is to be used in Europe must meet these specifications, which are somewhat different than those used in other countries.

See Table 4 for a list of commonly used European colorants. This list is based on the colorants approved in 94/36/EC (15).

Regulations for colorant use in Canada have many similarities to the U.S. regulations; however, differences do exist. Some colors approved in Canada are not approved in the United States and vice versa. Canada's color regulations for drug color generally list most colors

acceptable for use in Europe as well as those listed for use in the United States. However, some differences do exist. See Table 5 for colorants that can be used in Canadian drug applications (16).

In Japan, pharmaceutical colorants are regulated by the MHWs "Ministerial Ordinance to Establish Tar Colors which can be Used in Pharmaceuticals": No. 30, August 31, 1966 (17). This regulation provides a list of approved synthetic colorants and their specifications. In 1993, MHW reviewed these regulations, and proposals were made to update the regulation. However, no action has been

officially taken regarding these proposals at this time. Therefore, the 1966 regulation is still in effect. Quantity restrictions exist for most synthetic colorants in Japan based on a requirement that these colorants only be present in trace quantities. These trace requirements in Japan are commonly referred to as BIRYO limits. The BIRYO limit for the use of synthetic colorants in oral drug applications is not $>0.1\%$ by weight of color (lake or dye) in the dosage form.

Additional nonsynthetic colors may be acceptable for pharmaceutical applications based on previous precedence of use. These colors are typically listed in the Japanese Pharmaceutical Excipients (JPE) Directory along with their Japanese Pharmacopoeia (JP) or JPE specification (18).

See Table 6 for a list of commonly used pharmaceutical colorants in Japan. This list does not contain all of the acceptable colorants that may be used, but does highlight the major colorants with significant commercial implications along with some of the quantity restriction information.

Most countries have their own specific set of regulations concerning food and drug colorants based on local systems of additive approval. Because of these local evaluations, these regulations vary quite significantly and must be assessed when selecting colorants for target markets that include these countries.

Some countries throughout the world use colorants and specifications recommended by the JECFA, which is organized through the Food and Agricultural Organization (FAO) and the WHO (4, 5). In many cases, approved drug colors are considered by these countries to be the same as the approved food colors.

COLORING SYSTEMS FOR VARIOUS DOSAGE FORMS

Once the colorants have been identified that are approved for use in the target market, other performance-oriented criteria should be assessed. In selecting a colorant for a given application, prime consideration should be given to the type of formulation in which the colorant is to be incorporated.

Whatever the form of colorant chosen, it should meet certain criteria, namely:

- It must be nonreactive;
- It should be the most stable form for the application;
- It should be easily incorporated into the system in which it is being used;
- It should meet the aesthetic criteria required;
- It should not impart any offensive odor or taste to the product.

Tablets

Sugar-coating

Sugar-coating is a process involving several steps, and success is measured in terms of the elegance of the final product. To achieve this success, highly skilled manpower must be used, and care must be taken throughout the process. In the past, because of these factors, sugar-coating was a very time-consuming part of the manufacture of coated tablet dosage forms. The sugar-coating process is divided into several operations. These include sealing, subcoating, smoothing, coloring, and polishing.

For the purposes of this article, only the coloring stage will be discussed. This is probably one of the most critical parts of the operation. It gives the tablet its color and, in some cases, its finished size.

Before the 1950s, traditional color coating for solid dosage forms was usually performed using soluble dyes as the prime colorant. This system can produce the most elegant tablet. However, many difficulties can arise during the processing. These usually relate to the dye being soluble. Color migration readily occurs if the drying stage after each application of color is not handled properly. This results in nonuniform color or mottling. Small depressions or irregularities in the surface of the tablet may also cause nonuniform color. This results from the concentration of dye in these imperfections. Many smoothing coats are needed before any color can be applied.

Careful control must be exercised during the coating process to achieve a good color match. Care also must be taken to ensure that the tablets do not become overcolored. Syrups of increasing dye concentrations usually are used to achieve a color match and to control mottling. This operation may take from 20 to 60 applications for the color to develop fully.

All of the aforementioned problems combine to make color reproducibility from batch to batch difficult to achieve. It becomes obvious that the services of a skilled coater are needed to obtain the best possible results. As can be seen, dye sugar-coating is a very time-consuming and delicate operation.

Late in the 1950s, the pigment sugar-coating process was developed and subsequently patented by Arnold Nicholson and Stanley Tucker (19). The coloring composition of this invention was essentially an aluminum lake and an opacifier dispersed in a syrup solution. This system produced brightly colored, elegant tablets and eliminated many of the problems associated with the standard sugar-coating technique.

The use of insoluble certified lakes have several advantages; namely:

- The fact that they are insoluble enables the drying stages to be performed more quickly, because color migration is unlikely.
- Mottling is reduced because the opacity of the system minimizes the effect of tablet surface depressions.
- Overcoloring is not a problem because the system is opaque; hence, only one shade of color will result.
- Full color development can be achieved with a fewer number of application stages. This results in significant time savings, yet produces a final product that has all the properties of the standard sugar-coated tablet plus increased light stability. Raw material costs are also improved.
- Many of the problems associated with color reproducibility have been eliminated entirely. The finished tablet color has been predetermined by color matching the pigment dispersion before coating.

All of these advantages have resulted in pigment systems virtually replacing the soluble dye sugar-coating process.

Effective use of these pigments can be best made if they are adequately dispersed in the syrup. Obviously, it is more difficult to disperse pigment than it is to dissolve dye. The dusty nature of pigments sometimes requires the use of air filtration and dust collection systems to avoid contamination of other areas of the plant.

Today, there are a number of manufacturers who offer color-matched, predispersed, pigment sugar-coating concentrates. These concentrates are easily incorporated into the bulk of the syrup-coating solution. The convenience of these concentrates and the ability of the manufacturers to reproduce color batch after batch make these products an attractive alternative to self-preparation of dispersions.

Film-coating

Film-coating was developed early in the 1950s to help resolve many of the problems associated with sugar-coating. It involves the application of a film-forming polymer onto the surface of a substrate (such as tablets, granules, and capsules). In addition to the polymer, the film contains plasticizers and colorants, which are needed to achieve the desired properties in the final dosage form.

The polymer and the plasticizer are usually dissolved in a solvent to form a coating solution in which the colorants can be dissolved or dispersed. The original film-coating systems used organic solvents for polymer solution. Today, aqueous systems have largely replaced the organic solvents for environmental reasons.

When using organic solvents, water-soluble dyes are not used because of solubility constraints. In aqueous film-coating systems, water-soluble dyes can be used as colorants. However, many of the same problems observed

in sugar-coating may exist relating to color migration on drying of the films. Additionally, because film coatings are relatively thin, small differences in film thickness on tablets may result in significant color variations. There has been some success in using opacified dye systems; however, these systems have been shown to have poorer light stability than pigmented coatings.

The colorants of choice for these applications are lakes and inorganic pigments. In addition to providing color, pigments have been reported to reduce moisture diffusion through the film and improve light stability as compared with dye (20).

Again, it is important that these pigments be well dispersed in the system to maximize color and provide an elegant appearance. Because dispersing these pigments into the coating system is a difficult task, the use of commercially available predispersed color-matched pigment concentrates are recommended. These concentrates are available both in liquid and in dry forms. The dry forms may contain all of the components needed for a total film-coating system that can be dispersed in water or other solvents directly at the coating pan.

Colored wet granulations

Dissolving water-soluble dyes in a binding solution for the granulating process is the most common approach to coloring a tablet formulation. However, during drying of the granulation, the soluble colors may migrate, and if more than one color is used, the dyes may migrate at different rates. This results in an uneven coloring of the granulation, which will have a mottled appearance after compression. Some additives, such as starches, clays, and talc, have been used to adsorb the dye, thereby reducing but not completely eliminating the migration.

This entire problem can be avoided by using lakes or other pigments. The colors will not migrate because they are insoluble. In addition, the light stability of the product will be improved.

Direct compression

A growing interest in direct compression formulas has developed, mainly for economic reasons. The number of processing steps has been reduced, and the availability of many direct compression materials allows for a simplified tablet formulation. Direct compression formulations require blending only; therefore, lakes and other pigments are used because the elimination of the wetting step prevents the effective use of soluble colors.

The dry-coloring of tablets with pigments is not without problems. Although there is little chance of color migration, poor blending of the pigments into the powder can result in color specking and "hot spots." This problem

can be minimized by preblending the pigment with a small part of one of the other ingredients before addition to the entire mixture to reduce pigment particle agglomeration. The ease with which the pigment can be incorporated into the formulation may depend on the components in the mixture. In extreme cases, some type of milling may be required to achieve an adequate dispersion.

Hard Gelatin Capsules

Hard gelatin capsules are manufactured by melting gelatin, coloring the gelatin, and casting onto pins to form half capsules. They are then dried, stripped off, trimmed, and mated. The capsules are colored primarily using FD&C or D&C colorants and sometimes an opacifying agent such as titanium dioxide.

The clear type of capsule is colored using water-soluble dyes. Solutions of these colors are simply added to the gelatin melt. The pH of the gelatin is important because it can alter the shade of the color. It is also important to control the thickness of the capsule wall because variations can change color intensity. If the active ingredient is photosensitive, it is advisable to use an opaque capsule. Opaque capsules can contain pigments or dyes and an opacifier. The colorants are usually dissolved or dispersed in water, glycerine, or combinations of these vehicles before addition to the gelatin mixture. Wall thickness is rarely a factor in determining the shade of an opaque capsule.

Recent technological advances in the area of spin printing have allowed some manufacturers to color-identify capsules by printing bands of varying widths and colors on the capsule bodies through the use of colored imprinting inks. The inks are generally colored using pigments because they offer greater light stability. Dyes can be used, however, if a transparent color band is desired.

Liquid Products

The appearance of clear liquid products depends primarily on the color and clarity of the solution. Dyes should be used that are completely soluble in the particular solvent and at the required concentration. Many times dyes that correspond to the flavor of the product (for example, red for cherry or yellow for lemon) will be chosen.

Factors influencing the shade and stability of dyes in the liquid system must be carefully considered as well. Among these properties are pH, microbiologic activity, light exposure in the final product package, and the compatibility of the dye with other ingredients. The color shade of most dyes varies greatly at different pHs, making control of product pH extremely important.

All soluble dyes contain reactive sites, and some may be incompatible with drug substances in the formulation.

The anionic colors can also react with compounds containing polyvalent cations (such as calcium, magnesium, or aluminum) and precipitate. Certain dyes, such as FD&C blue #2 and FD&C red #3, exhibit such poor stability in aqueous solutions that they should never be used for coloring aqueous liquid products.

When formulating liquid products with dyes, the lowest possible concentration of dye needed to give the desired color should be used, because higher concentrations can result in a dull color. Most liquid products have dye concentrations of <0.001%. The actual concentration depends on how the product will normally be viewed and the depth of color required.

Because dyes are usually present in small concentrations, they should be predissolved before mixing with the bulk of the formulation. This will ensure that all the dye has been dissolved before additional processing. If the dye was added directly to the bulk mixing tank, the presence of small amounts of undissolved material would be difficult to determine and could cause additional problems later during the compounding procedure.

Pigments or dyes can be used for coloring opaque liquids such as suspensions, emulsions, or imprinting inks. In aqueous systems, pigments offer improved light stability and are less affected by pH and vehicle compatibility. This results in increased shelf life. In nonaqueous systems, because of solubility restrictions, the use of pigments is necessary. The liquid media may cause certain organic pigments to bleed. The extent of bleed will depend on the solvent composition and pH.

If pigments are chosen as the colorants, it may be necessary to predisperse them before adding them to the final product. Concentrated dispersions in a wide variety of vehicles are commercially available.

Ointments and Salves

Both dyes and pigments can be used for coloring ointments and salves, depending on the vehicle. Pigments are preferred because they will not migrate to the surface. To incorporate the pigments into the system, it may be necessary to blend the pigment and the product on a roll or ointment mill.

COLORANT PROPERTIES AND APPLICATIONS

Having discussed the different methods of coloring pharmaceutical products and the various forms of colorants available, the next section can be used to assist in product formulation.

Table 7 Approximate solubilities of some FD&C colors at 25°C in grams per 100 ml of solvent^a

Color	Distilled water	Glycerine	Propylene glycol	95% Ethanol	50% Ethanol
FD&C Blue #1	18	20	20	1.5	20
FD&C Blue #2	1.5	1	0.1	Trace	0.2
FD&C Green #3	17	15	15	0.2	7
FD&C Red #3	12	22	22	2	4
FD&C Red #40	20	3	1.5	Trace	1
FD&C Yellow #5	15	18	8	Trace	4
FD&C Yellow #6	18	15	2	Trace	2

^aThe solubility of commercial lots of FD&C colors differs widely depending on the amounts of salt, pure dye, moisture, and subsidiary dyes present.

Soluble Dyes

If the choice of colorant is a soluble dye, many are offered in a powder, granular, or liquid form. The liquid form offers ease of handling, is dust-free, and is ready to use. However, it is probably the most expensive form of coloring and is subject to both light and microbial stability problems. The powder form is least expensive but poses potential dust problems and can result in plant contamination. The granular product is recommended because dust problems are reduced, although, in some cases, it may have a slower rate of dissolution than the powder form, depending on the color.

Tables 7–9 show typical solubility and stability properties of some of the dyes.

Lake Pigments

FD&C lakes are available in dye strengths of 3–60%. The actual shade and tint will vary for each color and dye strength. There also may be slight differences from one manufacturer to another.

Properties that have made lakes more suitable (for coloring dosage forms) are their relative opacity, stability with regard to heat and light, and ability to be used dry when coloring products (such as tablets) made by direct

compression. They are the only choice for coloring fats and oils, because there are no oil-soluble colorants approved for this application.

Some of the physical characteristics listed for lakes in the literature include particle size distribution, moisture content, oil absorption, bulk density, specific gravity, and pH stability. These properties may or may not be of interest, depending on the user's application.

The particle size distribution determines the tinting properties of a particular pigment. A good distribution of particle size contributes to the relative ease of dispersion of the pigment into a given system.

If the lakes used are aluminum lakes, the alumina substrate contains water of hydration, and the lake itself may have total moisture content of between 12 and 25%. High processing temperatures can release some of the hydrated water; however, in most pharmaceutical applications this is not a problem.

Oil absorption is a measure of the amount of oil necessary to wet out a pigment particle such that each particle becomes enclosed in a shell of oil. The amount of oil required depends on the surface area of the pigment and the porosity of the particle. This property probably has more application in the paint industry than in coloring pharmaceuticals. It may be of some limited value in producing ointments and salves.

Table 8 FD&C color stability data

Dye	Heat	Light	Acid	Base	Oxidizing agents	Reducing agents

^aI—insoluble; SS—slightly soluble; F—fair; G—good; P—poor.

The bulk density is the mass of a unit volume of loose dry pigment, including voids. Sometimes this is called the apparent density. Bulk density may vary from one manufacturer to another, depending on the particular milling process.

Specific gravity is defined as the weight of pigment per unit volume relative to a standard, usually water. This property is important, because it can sometimes have an effect on dispersion stability. Pigments that are heavier than the vehicle in which they are dispersed are prone to settling.

Most aluminum lakes are within a pH range of 4.0–8.0. Outside this range, the dye and substrate may be separated and the lake dissolved. Other lakes may exhibit some stability outside of this range. The color shade of a lake may also vary with pH.

Table 10 gives typical physical properties for most FD&C lakes. Table 11 lists relative light stability information for some lake pigments. These values can

vary, depending on the environment in which the pigment is dispersed. The data shown relate fading properties of one pigment to another in a hydroxypropyl methylcellulose (HPMC) film system. This information can be used as a general guideline. However, actual light stability

Table 10 FD&C aluminum lakes: typical physical data

Average particle size	5.0–10.0 μm
Moisture content	12%–25%

Patent blue V, 25% AL	9

^aA hydroxypropyl methylcellulose film of pigment was exposed in a fadeometer for 3, 6, and 12 h. The rate at which the colorant degraded was noted from tint strength calculations and placed on a scale of 0–10, with the higher numbers indicating an increased tendency to fade. AL—aluminum lake.

information on a given dosage form must be evaluated when assessing shelf life and packaging concerns.

SUMMARY

As you can see, selection of colorants for use in global drug development can be very complicated and time-consuming. With the differences in colorant regulations worldwide and the need for various performance attributes based on the dosage form, there are numerous considerations that must be assessed. Therefore, it is important that appropriate expertise be consulted before finalizing colorant selection to help prevent future development or registration problems.

COLLOIDS AND COLLOID DRUG-DELIVERY SYSTEM

Diane J. Burgess

University of Connecticut, Storrs, Connecticut, U.S.A.

INTRODUCTION

The term *colloid* applies broadly to systems containing at least two components, in any state of matter, one dispersed in the other, in which the dispersed component consists of large molecules or small particles. These systems possess certain characteristic properties that are related mainly to the dimensions of the dispersed units. The colloidal size range is determined by two limits: the particles or molecules must be large relative to the molecular dimensions of the fluid in which they are dispersed so that the fluid can be assigned continuous properties; and they must be sufficiently small so that thermal forces dominate gravitational forces and they remain suspended. This sets the lower size limit at approximately 1 nm and the upper limit at approximately 1 μm . To qualify as a colloid, only one of the dimensions of the particle must be within this size range. For example, colloidal behavior is observed in fibers in which only two dimensions are in the colloidal size range. There are no sharp boundaries between colloidal and noncolloidal systems, especially at the upper size range. An emulsion system may display colloidal properties, yet the average droplet size may be larger than 1 μm . The word colloid was coined by Graham in 1861 from the Greek word for glue (*Rolla*) (1).

BIOLOGICAL AND PHARMACEUTICAL SIGNIFICANCE OF COLLOIDS

Many biological structures are colloidal in nature, such as blood (a dispersion of corpuscles in serum) and bone (a dispersion of calcium phosphate in collagen). There are also many macromolecular dispersions in the body, including enzymes and other proteins. Colloids are used medically for diagnostic imaging (radiolabeled, parenterally administered colloids), as adjuvants to improve therapy (to enhance the immune effect of various agents, such as toxins that are adsorbed onto a colloidal carrier), as a means of drug preparation (such as colloidal silver protein an effective germicide), in the preparation of dosage forms (e.g., the macromolecular colloid acacia is used as an emulsifying and suspending agent in creams, emulsions,

and suspensions), and as colloid drug-delivery systems (2–4) (including nanoparticle, microspheres, liposomes, and macromolecular drug complexes) for the purposes of drug targeting, controlled release, and protection of the drug substance. Colloid drug-delivery systems are used topically, orally, parenterally, and by inhalation. The reader is referred to the colloid drug-delivery system section of this article for further details on these systems.

CLASSIFICATION OF COLLOIDS

On the basis of interaction between the particles or macromolecules of the dispersed phase with the molecules of the dispersion medium, colloidal systems are classified into three groups: 1) *lyophilic*, solvent “loving” colloids, in which the disperse phase is dissolved in the continuous phase; 2) *lyophobic*, solvent “hating” colloids, in which the disperse phase is insoluble in the continuous phase; and 3) *association* colloids, in which the dispersed phase molecules are soluble in the continuous phase and spontaneously “self-assemble” or “associate” to form aggregates in the colloidal size range.

Lyophilic Colloids

The dispersed phase generally consists of soluble macromolecules, such as proteins and carbohydrates. These are thermodynamically true solutions; that is, they are best treated as a single phase system. The disperse phase has a significant effect on the properties of the dispersion medium and introduces an extra degree of freedom to the system. Lyophilic colloidal solutions are thermodynamically stable and form spontaneously when a solute and solvent are brought together. There is a reduction in Gibbs free energy (ΔG) on dispersion of a lyophilic colloid. ΔG is related to the interfacial area (ΔA), the interfacial tension (γ), and the entropy of the system (ΔS):

$$G = \gamma A - TS$$

where T is the absolute temperature.

The strong interaction between the solute and solvent usually supplies sufficient energy to break up the disperse

phase. In addition, there is an increase in the entropy of the solute on dispersion, which is generally greater than any decrease in solvent entropy. The interfacial tension (γ) is negligible if the solute has a high affinity for the solvent; thus, the $\gamma\Delta A$ term will approximate to zero. The shape of macromolecular colloids will vary with affinity for the solvent. Macromolecules will take on elongated configurations in a solvent for which they have a high affinity and will tend to decrease their total area of contact with a solvent for which they have little affinity by forming compact coils.

Lyophobic Colloids

The disperse phase is broken down into very small particles, which are distributed more or less uniformly throughout the solvent. The disperse phase and the dispersion medium may consist of solids, liquids, or gases and are two-phase or multiphase systems with a distinct interfacial region. As a consequence of the poor dispersed phase–dispersion interactions, lyophobic colloids are thermodynamically unstable and have a tendency to aggregate. The Gibbs free energy (ΔG) increases when a lyophobic material is dispersed throughout a medium. The greater the extent of dispersion, the greater the total surface area exposed and hence the greater the increase in the free energy of the system. When a particle is broken down into smaller particles, work is needed to separate the pieces against the forces of attraction between them (W). The resultant increase in free energy is proportional to the area of new surface created (A):

$$G = W = 2\gamma A$$

Molecules that were originally bulk molecules become surface molecules. In the surface environment the molecules have different configurations and energies than those in the bulk. An increase in free energy arises from the difference between the intermolecular forces experienced by surface and bulk molecules. Lyophobic colloids are aggregatively unstable and can remain dispersed in a medium only if the surface is treated to cause a strong repulsion between the particles. Such treated colloids are thermodynamically unstable yet are kinetically stable since aggregation can be prevented for long periods.

Preparation of lyophobic colloids

As a direct consequence of the thermodynamics of lyophobic colloidal systems, their preparation requires an energy input. If the dispersed phase is a solid, then particles may be produced by crushing, grinding, or controlled crystallization. The most direct method is by

grinding in a colloid mill (5–7). Coarse suspension particles are subjected to high shear by forcing them through a narrow gap between two rapidly rotating surfaces. The particles are torn apart by the shearing process. Ultrasonic energy may also be used to break up the disperse phase. Dispersing agents such as surfactants are often employed to prepare stable colloids. Surfactants reduce the interfacial tension and hence the free energy of the system.

Chemical methods of preparing lyophobic colloids include dissolution and reprecipitation, condensation from a vapor, and chemical reactions such as reduction, oxidation, and double decomposition. For example, mists or fogs may form spontaneously from a supersaturated vapor, provided that the degree of supersaturation is sufficiently high. Gold colloids can be produced by reducing chlorauric acid (HAuCl_4) with hydrogen peroxide or red phosphorous. Sulfur colloids can be produced by oxidation of hydrogen sulfide as follows:

The sulfur precipitate forms as a colloidal dispersion.

Emulsions

Emulsion systems can be considered a subcategory of lyophobic colloids. Like solid–liquid dispersions, their preparation requires an energy input, such as ultrasonication, homogenization, or high-speed stirring. The droplets formed are spherical, provided that the interfacial tension is positive and sufficiently large. Spontaneous emulsification may occur if a surfactant or surfactant system is present at a sufficient concentration to lower the interfacial tension almost to zero.

Clay minerals

Clay minerals such as silicates and kaolin form another subcategory of lyophobic colloids (5). Kaolin is used as a suspending agent in the preparation of dosage forms. Clays have a plate-like crystal habit. A kaolinite crystal is composed of alternate sheets of silica tetrahedra and alumina octahedra, which are bound by van der Waals forces and hydrogen bonding. The silicon–oxygen tetrahedra are linked to form hexagonal rings, and, in turn, these rings are linked to form a 2D sheet. Refer to the text by van Olphen (8) for further information on clay colloid chemistry.

Association Colloids

Association colloids are aggregates or “associations” of amphipathic surface active molecules. These molecules

are soluble in the solvent, and their molecular dimensions are below the colloidal size range. When present in solution at concentrations above a certain critical value (the critical micelle concentration), these molecules tend to form association colloids (micelles) (Fig. 1).

Amphipathic molecules consist of two parts: one of which has a high affinity for the medium (lyophilic), and the other has a low affinity for the medium (lyophobic). They tend to adsorb at interfaces to reduce the interfacial energy between the lyophobic portion of the molecule and the medium. On micellization the lyophobic portions of surfactant molecules associate to form regions from which the solvent is excluded, while the lyophilic portions of the molecules remain on the outer surface. The reader is referred to (9, 10) for the pioneering work in this area. Not all surfactants form micelles since a subtle balance between the lyophilic and lyophobic portions of the surfactant molecule is required. It appears that a charged, a zwitterionic, or a bulky oxygen-containing hydrophilic group is required to form micelles in an aqueous medium (11). These moieties are able to undergo significant hydrogen bonding and dipole interactions with water to stabilize the micelles. Micelle formation in strongly hydrogen-bonded solvents is very similar to that in water (11). Micelle formation is spontaneous, depending on the

lyophilic–lyophobic balance of the surfactant, surfactant concentration, and temperature.

At room temperature, micellization of amphipathic surfactants dissolved in water is driven by a significant increase in entropy. The hydrophobic part of the molecules induces a degree of structuring of water in the immediate area as a result of unfavorable interactions. This structuring disrupts the hydrogen-bond pattern and causes a significant decrease in the entropy of the water. This is known as the “hydrophobic” effect. The effect of temperature and pressure on micellization is dependent on surfactant properties (11, 12). Ionic surfactants generally exhibit a “Krafft” point. In these systems, micelles form only at temperatures above a certain critical temperature, the Krafft temperature. This is a consequence of a marked increase in the solubility of the surfactant at this temperature. Nonionic surfactants tend to behave in an opposite manner. Above a certain temperature (the cloud point), nonionic surfactants tend to aggregate and separate out as a distinct phase (13).

Micellar shape (Fig. 1) is dependent on surfactant concentration. At low concentration, the micelles are spherical, have well-defined aggregation numbers, and therefore are monodisperse. As the value is increased above the critical micelle concentration, micellar shape becomes distorted, forming cylindrical rods or flattened discs (14). At very high concentrations, liquid crystals form (15–17). Under specific conditions surfactants can form 2D membranes or bilayers separating two aqueous regions (similar to biological membranes). If this bilayer is continuous and encloses an aqueous region, then a vesicle results (liposomes). Insoluble drug substances can be solubilized within the interior of a micelle (Fig. 1). Micellar solubilization allows the preparation of water-insoluble drugs within aqueous vehicles (18). This is advantageous, particularly for intravenous delivery of water-insoluble drugs. Entrapment within a micellar system may increase the stability of poorly stable drug substances and can enhance drug bioavailability (19).

Fig. 1 Association colloids: (a) spherical micelle, (b) cylindrical micelle, (c) flattened disc-shaped micelle, (d) microtubular micelle, (e) inverted micelle, (f) micelle swollen by the presence of solubilized lipid soluble drug.

PROPERTIES OF COLLOIDS

The significant characteristics of colloids are particle size and shape, scattering of radiation, and kinetic properties.

Particle Size and Shape

The colloidal size range is approximately 1 nm to 1 μm and most colloidal systems are heterodisperse. Solid

dispersions usually consist of particles of very irregular shape. Particles produced by dispersion methods have shapes that depend partly on the natural cleavage planes of the crystals and partly on any points of weakness (imperfections) within the crystals. The shape of solid dispersions produced by condensation methods depends on the rate of growth of the different crystal faces. Treatments of particle shape are given by Beddow (20), Allen (21), and Shutton (22). The method of particle size measurement should reflect the aspect of the particle that is of most interest. This may be the surface area of the particle or its settling radius. To characterize hetero-disperse systems, it is necessary to determine the particle size distribution. Various theoretical distribution functions have been proposed such as the normal or Gaussian distribution and the log-normal distribution.

Microscopy

Most colloids are below the limit of resolution of the optical microscope but can be visualized by transmission electron microscopy (TEM) and scanning electron microscopy (SEM) (23, 24). TEM produces 2D images from which particle shape interpretation is difficult; however, size may be determined because of the high resolution. SEM produces 3D images. To obtain a value for the dimensions of an irregular particle, several possible measurements can be made (21). These include

1. Martin's diameter (d_m). This is defined as the length of a line that dissects the image of the particle.
2. Feret's diameter (d_f). This is defined as the distance between two tangents on opposite sides of the particle, which are parallel to some fixed direction.
3. Projected area diameter (d_a). This is defined as the diameter of a circle having the same area as the particle.

Ultracentrifugation

The Stokes settling radius of colloidal particles can be obtained from their sedimentation rate. An ultracentrifuge is used to increase the sedimentation rate (21), since colloidal particles settle very slowly under the influence of gravity alone.

Electronic pulse counters

Counters such as the Coulter Counter determine the number of particles in a known volume of an electrolyte solution. The suspension is drawn through a small orifice that has an electrode on either side. The dispersed phase particles interfere with current flow, causing the resistance to change. Resistance changes are related to the particle volume.

Light scattering

Both intensity and dynamic light scattering can be used as methods of particle size analysis of colloids. The simplest method is to measure the turbidity. Turbidity is defined as the reduction in the intensity of light as it passes through a colloidal sample. The loss in intensity is due to scattering of light and can be used to determine the average molar mass of a lyophilic colloid (25, 26). Dynamic light scattering, which is known as quasielastic light scattering or photon correlation spectroscopy, is used to obtain an estimate of the diffusion coefficient of a colloidal system, from which a particle radius can be determined by applying the Einstein and the Stokes equations (27, 28).

Hydrodynamic chromatography

To determine the particle size, a colloidal dispersion is forced through a long column packed with nonporous beads with an approximate radius of 10 μm . Particles of different size travel with different speeds around the beads and thus are collected in size fractions (29).

Scattering of Radiation

The scattering of a narrow beam of light by a colloidal system, such as a fog or a mist, to form a visible cone of scattered light is known as the Faraday–Tyndall effect (30, 31). The first detailed theory of light scattering by small particles was developed by Rayleigh in 1871. Light scattering theory was further developed by Mie (1908), Debye (1915), and Gans (1925). A full account of light scattering by colloidal systems is given in the texts of Hiemenz (26) and van de Hulst (25). When electromagnetic radiation falls on a material, oscillating dipoles are induced in the material. These serve as a secondary source of emission of scattered radiation with the same wavelength (λ) as the incident light. The intensity of the scattered light depends on the intensity of the original light, the polarizability of the material, the size and shape of the material, and the angle of observation. The scattering intensity increases with increases in the particle radius, reaching a maximum and then decreasing. Small particles ($\lambda/20 \geq r$) act as point sources of scattered light. In large particles, different regions of the same particle may behave as scattering centers. These scattering centers interfere with one another, either constructively or destructively. As particles become larger, the number of scattering centers increases, and the resultant destructive interference causes a reduction in the intensity of light scattering. As a consequence of these conflicting effects, visible light is scattered most intensely by particles within the colloidal size range.

Kinetic Properties

The kinetic properties of colloids are characterized by slow diffusion and slow, often negligible, sedimentation under gravity.

Thermal motion

The thermal motion of particles in the colloidal size range is known as Brownian motion (32, 33), after the English botanist Robert Brown who first observed the random directional movement of colloidal particles in 1827. The particles display a zigzag-type movement, which is a result of random collisions with the molecules of the suspending medium, other particles, and the walls of the containing vessel. The distance moved by a particle in a given period of time is related to the kinetic energy of the particle and the viscous friction of the medium. As a result of Brownian motion, colloidal particles diffuse from regions of high concentration to regions of lower concentration until the concentration is uniform throughout. Since diffusion is inversely related to particle radius, the diffusion of colloidal particles is relatively slow compared with that of small molecules or ions. Gravitational forces, which cause particles to sediment, and Brownian motion (diffusion forces) oppose one another. Colloids are of the size range at which the Brownian forces are stronger than gravitational forces, so they tend to remain suspended.

Osmosis

Osmosis is similar to diffusion in that the molecules move from a location of high chemical potential to one of low chemical potential. An osmotic pressure is generated in a colloidal solution when it is separated from its solvent by a barrier that is impermeable to the solute but is permeable to the solvent. The pure solvent will flow across the membrane, diluting the colloidal dispersion and, as the colloidal material cannot flow in the opposite direction, a pressure difference (osmotic pressure) will be created between the two compartments. Osmotic pressure is a colligative property and therefore can be related to the relative molecular mass of the colloidal material.

Viscosity

The viscosity of a system is a measure of its resistance to flow under an applied stress. Colloids, especially lyophilic colloids, tend to increase the viscosity of a system. The large molecular chains become entangled in one another, increasing the resistance to flow. The viscosity of a colloidal system is related to the shape, molecular weight, and concentration of the colloid. Viscosity measurement can be used to obtain an approximate molecular weight value.

LYOPHOBIC COLLOID STABILITY

There is a well-developed theory—the Derjaguin–Landau and Verwey–Overbeek (DLVO) theory—to describe the interaction between particles of a lyophobic colloid. This is reviewed in the texts of Hunter (1987) and Hiemenz (1986) and is based on the assumption that the van der Waals interactions (attractive forces) and the electrostatic interactions (repulsive forces) can be treated separately and then combined to obtain the overall effect of both of these forces on the particles.

Attractive Forces

van der Waals attractive forces between two particles are considered to arise from dipole–dipole interactions and are proportional to $1/H^6$, where H is the separation distance between the particles (34). These attractive forces were used to explain the phenomenon of colloid aggregation employing the Hamaker summation method to calculate the van der Waals interaction energy (V_A). This is based on the assumptions that the interactions between individual molecules in two colloidal particles can be added together to obtain the total interaction and that these interactions are not affected by the presence of all the other molecules. The modern dispersion theory of Lifshitz (35) overcomes the assumptions made in the London theory. The Lifshitz theory is based on the idea that the attractive interaction between particles is propagated as an electromagnetic wave over distances that are large compared with atomic dimensions. The colloidal particle is considered to be made up of many local oscillating dipoles that continuously radiate energy. These dipoles are also continuously absorbing energy from the electromagnetic fields generated by all the surrounding particles. Refer to Hunter (1987) for a full treatment of this theory.

Repulsive Forces

The electrostatic interaction between two colloidal particles is a consequence of the charge carried by the particles. All colloidal particles acquire a charge when dispersed in an electrolyte solution, by adsorption of ions from the solution onto the particle surface, by ionization of ionizable groups on the particle surface, or by selective ion dissolution from the particle surface (36). The charged particle surface attracts ions of the opposite sign (counter ions). This attraction is so strong that some of the counter ions are tightly bound to the particle surface. The counter ions also experience an attractive force, which

is exerted by the bulk solution and is caused by thermal motion. As a result of these two opposing effects, electrostatic attraction and thermal motion, a diffuse layer of ions builds up so that at a distance from the particle surface it appears to be electrically neutral. The tightly bound and the diffuse layers are known as the electrical double layer (30, 31). The repulsive interaction between the electrical double layers of two particles is caused by the free energy change involved when overlap occurs and the osmotic pressure generated by the accumulation of ions between the particles. The repulsive interaction (V_R) decreases exponentially with increase in the distance between the particles (30).

The DLVO theory is based on a combination of these two effects to explain the aggregative instability of two particles at any given separation distance. The resultant effect on the particles is calculated by summing these two opposing forces. This is shown diagrammatically in Fig. 2, where V_T is the summation of V_A and V_R ($V_T = V_A + V_R$). van der Waals attraction dominates at both large and small separation distances. At very small distances, van der Waals attraction increases markedly, resulting in a deep attractive well (known as the primary minimum). This well is not infinitely deep due to the very steep short range

Fig. 2 Potential energy of interaction (V_T) of two spheres of equal radius, obtained by the summation of van der Waals interaction potential energy (V_A) and the repulsive interaction potential energy (V_R) ($V_T = V_R + V_A$).

repulsion between the atoms on each surface (37). A complication to the DLVO theory is the influence of the surface on adjacent solvent layers (38). The DLVO theory can be applied in a broad sense to most systems, although the kinetics of aggregation may be uncertain.

Stabilization of Lyophobic Colloids

There are two methods of stabilization of lyophobic colloids: electrostatic and polymeric. Electrostatic stabilization results from charge–charge repulsion, as discussed previously. Polymeric stabilization is achieved by the adsorption of macromolecules (lyophilic colloids) at the surface of a lyophobic colloid (39, 40). Macromolecules of at least a few thousand molecular weight are required, as they must extend in space over a distance comparable to, or greater than, the distance over which van der Waals attraction is effective. The macromolecules must be mutually repulsive to impart colloid stability. This is achieved when they are present at a sufficiently high concentration that they saturate the surfaces of the particles (39). The colloidal particles will then repel one another as a result of volume restriction and osmotic pressure effects as a result of the high concentration of polymer chains in a confined area (Fig. 3). Hunter (37) gives a thermodynamic account of polymeric stabilization. At low polymer concentrations (and hence low particle surface coverage), bridging flocculation may occur (Fig. 4). Bridging is a consequence of the adsorption of segments of an individual polymeric flocculant molecule onto the surface of more than one particle. A polyelectrolyte may stabilize a lyophobic colloid by a combination of steric and electrostatic stabilization, “electro-steric” stabilization.

Fig. 3 Steric stabilization of lyophobic colloidal particles. The particles repel one another because of volume restriction and osmotic pressure effects.

Fig. 4 Bridging flocculation. Lyophobic particles are bound together by the adsorption of polymer chains.

COLLOID DRUG-DELIVERY SYSTEMS

Colloid drug-delivery systems are used to increase the bioavailability of drug substances, to improve drug stability, to sustain and control drug-release rates, to target drugs to specific sites in the body, and to stimulate the immune system. Rate-controlled delivery can be achieved by delayed diffusion through a polymer matrix. The reader is referred to the article in this Encyclopedia on Microsphere Technology and Applications for details on controlled release from polymer microspheres (41). Rate-controlled delivery allows drugs with short biological half-lives and narrow therapeutic indices to be utilized. Drug targeting can improve the therapeutic index of a drug by optimizing the access, amplitude, and nature of interactions with the pharmacological receptor. Drug targeting can also protect the drug and the body from any unwanted and deleterious disposition. Biotechnological therapeutics are ideal candidates for site-specific delivery as these are very potent substances and are rapidly proteolytically degraded after administration. Encapsulation within a colloidal system can protect these therapeutic agents from degradation and deliver them to their sites of action. Drug targeting may be simply targeting a particular body compartment, such as the knee joint. This can be achieved by passive targeting via direct injection into the joint cavity (intra-articular injection). Greater specificity may be required, such as delivery to a particular organ, to a set of cells within an organ, or even to an intracellular structure. This usually requires active targeting, meaning that the natural distribution of the carrier is altered. In some cases it is possible to target to specific cells or intracellular structures by exploiting a natural physiological process such as macrophage uptake of foreign materials.

Colloid drug-carrier systems are of two types: particulate carriers (capsular, monolithic, or cellular) and soluble carriers (macromolecular drug conjugates). The pioneering work on soluble carrier systems was carried out by Ghose and Cerini (42), on radioimmunolocalization of tumors through the use of antibodies, and by Ghose and Nigam (43) and Rowland et al. (44) on drug-antibody conjugates. Particulate-carrier systems, including liposomes, microspheres, nanoparticles, microemulsions, erythrocytes, and vaccines, have been used as a means of drug targeting. The use of liposomes (phospholipid vesicles) for drug targeting was proposed by Sessa and Weissmann (45) and Gregoriadis et al. (46).

The fate of intravenously administered colloidal particles is controlled by particle size and particle surface properties. Particles larger than 7 μm are rapidly filtered by the fine capillary beds of the lung (2, 46, 47). Particles (100 nm to 7 μm) are rapidly taken up by the cells of the reticuloendothelial system (RES) if they are recognized as foreign (48, 49). Particle size can thus be utilized as a means of passive targeting. To target specific cells in other organs, colloidal carriers must escape from the vascular compartment (extravasate). This is generally difficult to achieve, as the plasma membrane is usually continuous and impermeable to large molecules and small particles. Molecules (5000–10,000 Da) may pass into the interstitial space to be collected by the lymphatic system. Some capillary membranes are fenestrated, containing small holes (fenestrae) 50–60 nm in size, which allow small particles to pass through. Sinusoidal or discontinuous membranes are present in the parenchymal cells of the liver, spleen, and bone marrow. These membranes have gaps of the order of 150 nm. Fenestrations may also occur in areas of tissue inflammation and infection (50); hence, the uptake of colloid carrier systems may be enhanced in these areas. The intracellular transport of certain drug-carrier complexes may occur via endocytosis (51). Endocytotic vesicles form at cell surfaces for the purpose of transporting fluids (pinocytic vesicles) and solids (phagocytic vesicles) into the cells and through the cells to the opposite membrane. Receptor-mediated transcytotic routes exist for certain macromolecules, and these can be exploited for the purpose of drug delivery.

Targeting the RES

Passive targeting to the RES can be utilized to treat diseases of the RES (neoplasms and parasitic, viral, and bacterial infections) and for macrophage stimulation to treat pulmonary metastases (52). Liposomes have been used to target antimony compounds to the liver and to treat leishmaniasis (53), and nanoparticles have been used to

target the flukicide nitroxylin (54) to the liver. Various carrier systems have been used to target cytostatic agents to the RES to treat monocytic leukemia, histiocytic medullary reticulosis, and certain forms of Hodgkins disease (55). Macrophages are the primary barrier against the growth and metastatic spread of neoplastic cells (56–58). Macrophage-activating factors (such as, muranyl di- and tripeptides, modified lymphokines, and interferon) that activate the macrophage to the tumoricidal state can be incorporated into colloidal systems (such as liposomes), and thus these agents will be taken up at their active site (the macrophage). Fidler (59) has successfully delivered lymphokines to activate macrophages to abrogate the development of micrometastases after surgical removal of a primary tumor.

Avoiding the RES

Colloidal properties that influence RES uptake are particle size, surface charge, surface hydrophobicity, and the adsorption of macromolecules onto the particle surface. The surface of colloidal particles can be altered to avoid RES uptake by adsorption or grafting of a hydrophilic polymer onto the surface of a particle and thereby creating an energy barrier to particle interaction (e.g., the nonionic surfactant Tween 20 can be adsorbed) (60). Both biological and synthetic polymers have been used for RES masking of colloidal particles, for example, albumin (61), immunoglobulin G (62), carboxymethylcellulose (63), poloxamers (64, 65), and poloxamines. RES uptake can also be avoided by saturating the RES with placebo colloidal particles prior to the administration of the colloidal carrier system (66). However, blockade of the RES is not clinically acceptable.

Types of Colloidal Carrier Systems

Soluble-carrier systems

At least three types of polymer–drug conjugate systems exist: 1) those active at the cell surface, 2) those active following endocytic capture by cells, and 3) those capable of releasing drug extracellularly in a controlled manner (67). Targeting to the cell surface can be achieved by utilizing the specific properties of the target cell. Antibodies specific for a variety of cell surface determinants on neoplastic B cells, such as sIgD or the sIg idiotype, can be complexed to drugs, toxins, or isotopes. Although drug–antibody conjugates have the ability to target tumor sites, the linking procedure may result in inactivation of the drug or of the antibody (68). Monoclonal antibodies can react with normal tissue, and

immune responses may occur. Tumor heterogeneity also causes problems with this approach to drug targeting. Specific intracellular drug action can be achieved through endocytosis of drug–carrier conjugates. Specific receptors exist for various macromolecules, and these can be exploited to achieve intracellular transport of drugs. Dextran have been used to deliver drugs extracellularly (69).

Particulate-carrier systems

Liposomes: These are artificial lipid vesicles consisting of one or more lipid bilayers enclosing a similar number of aqueous compartments (70). Liposomes can be subcategorized into 1) small unilamellar vesicles (SUV), 25–70 nm in size, that consist of a single lipid bilayer, 2) large unilamellar vesicles (LUV), 100–400 nm in size, that consist of a single lipid bilayer, and 3) multilamellar vesicles (MLV), 200 nm to several microns, that consist of two or more concentric bilayers. Unmodified liposomes passively target the Kupffer cells in the liver (71) and have been used to target drugs to the liver. SUVs may target the liver parenchymal cells, as they pass through the “sieve plates.” Liposomes are relatively unstable, have low carrying capacities, and tend to be “leaky” to entrapped drug substances. The properties of liposomes can be altered by the incorporation of various molecules such as cholesterol, cetylphosphate, and stearylamine into the phospholipid bilayer. The presence of cholesterol results in a more stable, less “leaky” membrane. Polymerized liposomes have been developed that are more stable and less “leaky.” These are composed of phospholipids with polymerizable moieties. Immunoglobulins have been attached to the surface of liposomes to actively target them to specific sites. Polyethylene glycol-coated (pegylated) liposomes, also known as “stealth” liposomes, have been prepared, which have extended biological half-lives (72–74). As a consequence of the polyethylene glycol coating these liposomes are able to avoid RES uptake. Liposomes prepared with cationic and fusogenic lipids are currently being utilized in gene therapy to deliver DNA into target cells (75–77). The cationic lipids bind with the DNA and the fusogenic lipids are able to fuse with cell membranes, allowing the DNA to be introduced into cells.

Emulsions (lipid microspheres): Colloid-sized emulsion droplets are used in drug delivery to solubilize water-insoluble drug substances and for the purposes of controlled and sustained release and drug targeting. Fat emulsions such as intralipid are used for parenteral nutrition (78). The stability of parenterally administered emulsion droplets is dependent on the nature of the emulsifying agent used and on the presence of minor

components. Emulsion droplets are usually taken up by the cells of the RES. Lecithin is most frequently used to stabilize parenteral emulsions. The coalescence and behavior of oil droplets stabilized by phospholipid emulsifiers have extensively studied by Davis and Hansrani (79). The deposition of emulsion droplets is dependent on the charge carried by the droplets and the nature of the oil phase. Emulsions of vegetable oils are preferentially deposited in adipose tissue, lactating mammary glands, and myocardium muscle (80). Interaction of emulsions with macrophage cells can be reduced by coating with hydrophilic polymeric materials. Drug-release rates from emulsions are controlled by the particle size of the dispersed phase and emulsion viscosity. Lipid emulsions are very stable, can be stored for 2 years at room temperature (81), and have a low incidence of side effects, even at doses of 500 ml (which are typically given for parenteral nutrition purposes). Emulsion systems for IV nutrition and drug delivery have been reviewed recently by Lyons and Carter (82).

Lipoproteins: These are natural body transporters for cholesterol, triacycloglycerols, and phospholipids. These include high-density lipoproteins (HDL), 10 nm in size; low-density lipoproteins (LDL), 23 nm in size; and very low density lipoproteins (VLDL), 30–100 nm in size (83). LDL has been targeted into endothelial cells (84), and trigal-chol LDL has been targeted into Kupffer cells (85). The use of lipoproteins for site-specific delivery has been reviewed by Vitols et al. (86).

Microspheres: Microspheres are usually solid, approximately spherical particles containing dispersed drug in either solution or microcrystalline form. Incorporation of drugs can be achieved by entrapment during production (polymerization, gelation, or encapsulation techniques, such as coacervation and phase separation) and by covalent and ionic attachment. The drug-loading capacities are usually fairly high, up to 50%. Microspheres may be prepared from natural polymers such as gelatin and albumin (87, 88) and from synthetic polymers such as polylactic and polyglycolic acid. The drug is either totally encapsulated within a distinct capsule wall or is dispersed throughout the microsphere. Drug release is controlled by dissolution and diffusion of the drug through the microsphere matrix or the microcapsule wall, or by polymer degradation. Microspheres range in size between approximately 1 and 1000 μm . Consequently, these systems are outside the conventional colloidal size range. In the pharmaceutical literature, however, microcapsules with sizes up to approximately 15 μm are considered as colloidal-delivery systems. Magnetic microspheres composed of albumin and iron oxide have been used as a means of targeting specific areas in the body (89). Polymeric

microsphere systems have been reviewed by Davis et al. (2) and Benita (90).^a

Nanoparticles: Nanoparticles are similar to microspheres but have particle sizes in the nanometer range (10–1000 nm). It is unlikely that nanometer-sized polymeric systems are “capsule-like” and have discrete shells. Nanoparticles can be made from nonbiodegradable materials, such as methylmethacrylate (91), or from biodegradable materials, such as alkylcyanoacrylate (92) and albumin. Widder (89) prepared magnetic albumin microspheres containing Fe_3O_4 in the size range 10–20 nm. Nanoparticles are used for drug targeting, both active and passive. The relatively small size of these systems limits their use, as only small quantities of material can be encapsulated. Other types of (nonbiodegradable) nanoparticle systems include colloidal sulfur and colloidal gold. Colloidal sulfur is used as a diagnostic agent (labeled with $^{99\text{m}}\text{Tc}$). It is usually protected from aggregation by the addition of gelatin as a polymeric stabilizer. Colloidal gold is also used as a diagnostic (^{198}Au) and as a therapeutic agent (93). Again, gelatin is used as a stabilizer. Heat denatured macroaggregated $^{99\text{m}}\text{Tc}$ albumin spheres are used as diagnostic agents. Polyacrylamide nanoparticles containing fluorescein have been used to monitor cellular processes (92). Diagnostics can be passively or actively targeted. Particle coating to avoid RES uptake has been utilized to achieve targeting of diagnostic agents to the bone marrow (90). Nanoparticles are also used as immune adjuvants. Polymethylmethacrylate nanoparticles have been shown to possess adjuvant activity for tetanus toxoid (92) and for influenza virus (94). The adjuvant effect was equal to or better than that of colloidal aluminum hydroxide particles, the traditional adjuvant.

Viruses: Viruses provide a unique and extremely efficient method of insertion of genes into mammalian cells, such as human bone marrow stem cells (95). SV 40, adenovirus, vaccine virus, and polyomavirus have been used as gene transfer vectors. A nonreplicating adenoviral vector that efficiently infects human cells has recently been developed (96). The essential feature of a retroviral gene delivery system is the presence of an RNA copy of the replacement gene that is packaged in a viral particle, capable of specific and efficient entry into the cytoplasm of a cell (97). A retrovirus consists of an RNA-protein core encapsulated in a lipid envelope. The viral glycoproteins bind with specific receptors on the target cells, and the virus envelope then fuses with the cell membrane, resulting in the introduction of the RNA genome into the cytoplasm. This method of gene insertion

^aSee *Microsphere Technology and Applications*, page 1793.

is not normally harmful to cells. Potential problems include deletion of sequences during replication, recombination with endogenous viral sequences to produce infectious recombinant viruses, activation of cellular oncogenes, introduction of viral oncogenes, and inactivation of genes.

Ideal Properties of Drug-Carrier Systems

The drug carrier should accumulate selectively at the required site, achieve sufficient drug loading, be able to release the drug at the appropriate rate at the site of action, be stable in vitro and in transit to the target site in vivo, be biodegradable, be nontoxic and nonimmunogenic, be easy and inexpensive to prepare, and be sterile for parenteral use.

COMPLEXATION AND CYCLODEXTRINS

Gerold Mosher

Diane O. Thompson

CyDex, Inc., Overland Park, Kansas, U.S.A.

INTRODUCTION

Complexation is one of several ways to favorably enhance the physicochemical properties of pharmaceutical compounds. It may loosely be defined as the reversible association of a substrate and ligand to form a new species. Although the classification of complexes is somewhat arbitrary, the differentiation is usually based on the types of interactions and species involved, e.g., metal complexes, molecular complexes, inclusion complexes, and ion-exchange compounds. Cyclodextrins (CDs) are classic examples of compounds that form inclusion complexes. These complexes are formed when a "guest" molecule is partially or fully included inside a "host" molecule e.g. CD with no covalent bonding. When inclusion complexes are formed, the physicochemical parameters of the guest molecule are disguised or altered and improvements in the molecule's solubility, stability, taste, safety, bioavailability, etc., are commonly seen.

CDs form inclusion complexes with many different types of compounds, thus their potential as formulation additives has been investigated for over 40 years. They were discovered in 1891 when Villiers (1) observed crystallization occurring in a bacterial digest of starch. Schardinger's (2) evaluation of the unusual crystalline dextrins in 1903 suggested their cyclic nature but their complete structural definition did not occur until the 1940s (3, 4). This coincided with the identification of the enzyme responsible for their production (*Bacillus macerans* amylase, now referred to as cyclodextrin glucosyltransferase: CGTase: EC 2.4.1.19), and the recognition of the complexing properties of the CD cavity. In the next 30–40 years, extensive work resulted in the ability to produce each of the parent CDs in bulk quantities.

With improvements in the cost and availability of the parent CDs came increases in the volume of scientific investigation. Limitations in the pharmaceutical utility of the CDs were becoming known and derivatives were prepared with the goal of improving characteristics such as complexing ability, solubility, and safety.

Biennial international conferences (5) and reviews (6, 7) have presented the latest research in the production, characterization, and utilization of CDs in biomedical

products, foods, and cosmetics. A literature search of the 19-year period from 1967 to 1985 yields approximately 400 journal references describing CDs in pharmaceutical applications. Uekama and Otagiri (8) reviewed over half of this published literature in 1986. A search of the literature since 1986 shows that journal references have more than tripled and the patent literature has continued to grow rapidly (Fig. 1). Scientific articles have established the research applications of CDs but it is the patents that have shown the increasing interest in the commercial protection of CDs in pharmaceutical products.

The commercial viability of a CD formulation has been established with the marketing of 20 products (Table 1). Two of these products are currently on the market in the United States; one product (oral and parenteral formulations) containing a derivatized CD and the other containing α -CD. Numerous clinical trials using CD formulations have, however, been conducted or are in progress in the United States, with at least one other NDA under review.

Increasing numbers of pharmaceutical products are reaching the market place as CD formulations and research studies exploring their applications are growing exponentially. Nevertheless, the routine use of CDs in formulations is still questioned. The reluctance to develop a CD formulation is mainly due to the uncertain regulatory acceptance of a formulation containing a "nonstandard" inactive ingredient.

INCLUSION COMPLEXATION AND CDs

CDs are cyclic oligosaccharides containing 6, 7, or 8 glucopyranose units, referred to as α -, β -, or γ -CD, respectively. Each glucose unit contains two secondary alcohols at C-2 and C-3 and a primary alcohol at the C-6 position, providing 18–24 sites for chemical modification and derivatization (Fig. 2). Numerous derivatives have been prepared and described in the literature, but because of all the possible derivatives and positional and regioisomers, appropriate nomenclature must be used. The nomenclature should include at a minimum, the parent CD (α , β , or γ -CD) and the type and number of

Fig. 1 Patents and patent applications in the use of CDs in pharmaceuticals. (Data collected from *Chemical Abstracts* 1967–1999.)

substituents. The substituents are usually noted by an abbreviation placed before the parent CD. Further description of the substituent group can be included with the abbreviation, if needed. For example, the hydroxyl group on the hydroxypropyl substituent can exist at one of three carbons in the propyl chain. This isomeric position is noted by a number preceding the HP notation and enclosed in parentheses. The most commonly occurring HP derivative is the (2HP)- β -CD, which is often referred to as HP- β -CD.

The number following the abbreviation of the substituent indicates the average number of substituents on the molecule, rounded to the nearest whole number. For example, HP4- β -CD indicates a β -CD with an average of four hydroxypropyl substituents. This is referred to as the molar degree of substitution (MS). It is simply a statement of the molar ratio of substituent to CD. The four substituents might be located on four different hydroxyl functionalities around the CD ring or, at the other extreme, one hydroxyl might be derivatized with a chain of four HP units. Adding further confusion is the fact that the MS can refer to the average molar degree of substitution around the CD ring, or only around each glucose ring. The latter interpretation is a carry-over from traditional carbohydrate chemistry where the lengths of the glucose chains (i.e., the molecular weights) were often not well characterized.

A similar term, the degree of substitution (DS) describes the average number of hydroxyls derivatized. Unfortunately, it has also been used to describe both the average number of hydroxyls around the CD ring and the average number around each glucose ring. A clarifying proposal to use RS (ring substituents) to designate the average number of hydroxyls derivatized in the entire CD ring and DS, the number around each glucose ring, has not been broadly embraced. The term MS will be used here

and will denote the average molar degree of substitution around the CD ring.

Regardless of which convention is used for degree of substitution, none provide any indication of the position of these substituents on the glucopyranose units. If it is known, the position of the substituent on the glucopyranose unit is indicated by a number preceding the substituent abbreviation. 6-SBE1- β -CD describes the monosubstituted sulfobutyl ether derivative with the substituent attached at one of the C-6 positions. More often than not, the substituent is introduced in a random reaction process such that introduction occurs with some defined distribution at the 2-, 3-, and/or 6-positions. For these preparations, no number precedes the substituent abbreviation. HP4- β -CD implies a tetra-substituted hydroxypropyl preparation with substituents randomly distributed over all three positions of the seven glucopyranose units. A number of common CDs and their nomenclature are given in Table 2.

The 3D structure of the parent CD provides a cavity (Fig. 3) that is hydrophobic relative to an aqueous environment. The sequestration of hydrophobic drugs inside the cavity of the CD can improve the drug's solubility and stability in water, the rate and extent of dissolution of the drug:CD complex, and the bioavailability of the drug when dissolution and solubility are limiting the delivery. These properties of the CDs enable the creation of formulations for insoluble drugs typically difficult to formulate and deliver with more traditional excipients. Numerous CDs that have different complexing abilities are available. A quantitative determination of their complexing properties is necessary for proper evaluation.

CDs form inclusion complexes with hydrophobic drugs through an equilibrium process (Fig. 4), quantitatively described in Equation (1) by an association or stability constant ($K_{a:b}$),

$$K_{a:b} = \frac{[Drug_a CD_b]}{[Drug]^a [CD]^b} \quad (1)$$

where a and b represent the molar ratio of the sequestered drug molecule to the CD. The magnitude of this associate constant can be used to compare the binding effectiveness of different CDs. Various complexes with different ratios of drug-to-CD molecules can be formed, depending on the type of CD used and the size and physicochemical characteristics of the drug molecule. In dilute solutions and/or if the drug fits entirely into the CD cavity, a 1:1 complex results. However, if the cavity is large enough, two drug molecules may be accommodated, resulting in the formation of a 2:1 complex. Conversely, if the drug is

very large, then several CD molecules might enclose the drug for the formation of 1:2 or higher order complexes. Although each complex has a finite stoichiometry, more than one complex may be formed in a given system. Depending on the method used to determine the association constant, it is possible to obtain a description of the stoichiometry of the complex ($a:b$).

Evaluating Inclusion Complexation

One of the most common methods of determining association constants and stoichiometry is the phase solubility technique (9). The technique involves adding an equal weight (in considerable excess of its normal solubility) of the compound to be complexed into each of several vials or ampoules. A constant volume of solvent is added to each container. Successively increasing portions of the complexing agent are then added to the vessels. The vessels are then closed and the contents brought to solubility equilibrium by prolonged agitation at constant temperature. The solution phases are then analyzed for total solute content. A phase diagram is constructed by plotting the molar concentration of dissolved solute, found on the vertical axis, against the concentration of complexing agent added on the horizontal axis. Two general types of phase solubility profiles are generated; Type A where soluble complexes are formed, and Type B where complexes of limited solubility are formed.

In Type A diagrams, an increase in solubility of the compound occurs as the amount of complexing agent increases. Soluble complexes are formed between the compound and the complexing agent, thereby increasing the total amount of compound in solution. Depending on the nature of the complexes formed, the diagram can be

linear, A_L , or show curvature in a positive, A_P , or negative, A_N , fashion (Fig. 5). Linear diagrams are formed when each complex contains only one molecule of complexing agent. When more than one molecule of complexing agent is found in the complex, an A_P -type diagram is formed. A_N diagrams are uncommon but may result if self-association is present or high concentrations of complexing agent cause alterations in the nature of the solvent.

Type B diagrams are observed when complexes of limited solubility are formed. In Fig. 5, the segment xy in curve B_S shows the formation of a complex that increases the total solubility of the compound. This is similar to a Type A diagram. At point y , however, the solubility of the complex is reached and as additional compound goes into solution, some solid complex precipitates. At point z , all of the excess solid compound added to the vials has been consumed by this process. Further addition of complexing agent beyond point z results in depletion of the compound from solution by complex formation. Curve B_I is interpreted in a similar manner except that the complex formed is so insoluble that no increase in solubility is observed.

The stoichiometry of the complexes can often be determined from the ascending and descending portions of these diagrams if certain assumptions can be made (9). If a 1:1 complex is formed, the association constant $K_{a:b}$ can be determined from the slope of the initial linear portion of the phase solubility curve, and the intrinsic solubility of the compound, S_0 , using Equation (2):

$$K_{1:1} = \frac{\text{Slope}}{S_0(1 - \text{Slope})} \quad (2)$$

Additional methods are available to determine these association or stability constants including spectroscopy [UV (10, 11), fluorescence (12, 13), NMR (14), and ORD-CD (15, 16)], potentiometry (17), microcalorimetry (18, 19), surface tension (20), membrane permeation (21), electrophoresis (22, 23), and freezing point depression (24). Chromatographic methods include HPLC (25), paper (26, 27), and TLC (28, 29) techniques.

The binding constants obtained by different methods often correlate. For example, diazepam forms a complex with β -CD with an association constant of 220 or 208 M^{-1} as determined by phase solubility (30) vs. circular dichroism (31). There is a close correlation of the binding constants (32) for bendroflumazide and cyclopentiazide as determined by the phase solubility method (56 and 165 M^{-1}) and UV method (60 and 178 M^{-1}).

However, while the above methods gave similar results, the association of β -CD and FCE24578 (17), a synthetic immunomodulator, exhibits a binding constant of 690 M^{-1}

(Adapted from Ref. 6.)

by a phase solubility determination but a binding constant over four times higher with a UV method. This discrepancy is due to the fact that higher order complexes contribute to spectral changes and these have not been accounted for in the calculation of the UV association constant. Inconsistencies are also observed between binding constants determined by fluorescence intensity and HPLC methods in the binding of estradiol, ethinylestradiol, and estriol, to β - and γ -CD (12). The fluorometric association constants with β -CD were lower than the corresponding HPLC values, whereas for the

**Fig. 3** Complexation of drugs inside the hydrophobic cavity of CDs.

Fig. 4 Equilibrium process describing the interaction between a CD and an insoluble drug molecule to form a soluble or insoluble complex. (Modified from Ref. 6.)

complexes with γ -CD the results of both methods coincide.

pH conditions have also been observed to exert a unique effect on one method and not the other. Doxorubicin (33) and γ -CD form a complex with a $K_{1:1}$ of 617 and 718 M^{-1} as measured at pH 10 by UV and circular dichroism. This close correlation was not observed when the measurements on doxorubicin were conducted at pH 7. At pH 7, the binding constant for doxorubicin (34) was 235 M^{-1} as measured by UV but was 977 M^{-1} as measured by circular dichroism. Under a given set of conditions, a drug has only one binding constant. Therefore, this difference is reflecting how the ionization state of the drug affects the analytical measurements.

In general, binding constants can be used as an indicator of differences in binding only if the methods or conditions for determining the constants are equivalent or unaffected by the conditions. And although determining values by phase solubility might be appropriate for formulation studies, it is probably not appropriate for determination of true thermodynamic values due to the concentrations involved.

Factors Affecting Complexation

Steric effects

Cyclodextrins are capable of forming inclusion complexes with compounds having a size compatible with the dimensions of the cavity. Complex formation with molecules significantly larger than the cavity may also be possible in such a way that only certain groups or side chains penetrate into the carbohydrate channel. The three natural CDs, α , β , and γ , have different internal diameters and are able to accommodate molecules of different size. Cyclohexane is able to complex with all three CDs, but because of size naphthalene does not complex with α -CD, which has the smallest cavity. Anthracene fits only into γ -CD, which has the largest cavity.

Derivatization of the hydroxyls on one or both faces of the natural CD can impact the steric requirements for an acceptable guest molecule. The presence of bulky groups can sterically block entrance to the CD cavity. However,

Fig. 5 Possible types of phase solubility diagrams.

some groups, depending on their number, flexibility, and position of attachment, may actually act to extend the cavity and provide for better complexation. Substitution at the 3- and 6-positions will be more likely to narrow the cavity opening while substitution at the 2- and 6-positions may allow for extension of the opening. The binding constants of flurbiprofen (35), bromazepam (36), and nitrazepam (37) to 2,6-DM- β -CD (methyl substituents in the 2- and 6-positions) are 2.3-, 2.9-, and 3.8- fold higher, respectively, than their binding to β -CD. Binding to 2,3,6-TM- β -CD (methyl substituents in the 2-, 3-, and 6-positions), however, shows constants that are less than half of that observed with β -CD.

The numbers of substituents added to the ring (MS) can also affect binding in both positive and negative manners. Müller and Brauns (38) showed that increasing the MS from 3 to 11 decreased the solubilization of hydrocortisone from 10.98 to 5.76 mg/ml for a 0.04 M HE- β -CD (hydroxyethyl) solution ($\sim 5\%$ w/v). A similar effect was observed for digitoxin, diazepam, and indomethacin. The decrease in solubilization was thought to be due to steric hindrance of the increased number of HE substituents. An additional explanation may be that some polymerization of the HE groups may have occurred during preparation of the higher MS products, thereby creating bulkier side chains that may have crowded the cavity entrance.

The hydroxypropyl substituent, being larger yet, appears to require a lower DS to improve binding without sterically obscuring the cavity entrance. Müller and Brauns (38) have studied the effect of the DS on complexing ability (Table 3) and have observed that lower degrees of hydroxypropyl substitution (2 to 5) are more conducive to complexation. As the DS increases, the solubilization of six different drugs decreases but when the DS is from 4 to 8 the solubilization is fairly consistent.

Table 3 Effect of degree of substitution on complexation of drugs by HP- β -CD

(Adapted from Ref. 39.)

There is a compromise between the steric hindrance of a substituent and its ability to extend the hydrophobic cavity. Yoshida et al. (40) have shown that introduction of the 3-hydroxypropyl (3HP) substituent ($-\text{O}-\text{CH}_2-\text{CH}_2-\text{CH}_2-\text{OH}$) at an MS of ~ 6 results in higher binding constants than those observed with β -CD, apparently due to the extension of the hydrophobic cavity. The introduction of an equivalent number of 2,3-dihydroxypropyl (2,3-DHP) substituents ($-\text{O}-\text{CH}_2-\text{CH}(\text{OH})-\text{CH}_2-\text{OH}$), however, results in a decrease in the binding constants. This was speculated to be due to steric hindrance of the larger 2,3-DHP substituent, though this group, being more hydrophilic than 3HP, may not serve to extend the hydrophobicity of the cavity.

There is also a compromise between the ability to form complexes and the intrinsic water solubility. Rao et al. (41) have shown that increasing the DS of (2HP)- β -CD improves the aqueous solubility but impairs the complexation capability. Fig. 6 shows this affect for the complexation of phenolphthalein.

Greater steric interferences would be anticipated for the bulkier charged sulfoalkyl ether groups, but have not been observed. Kano et al. (42) evaluated the use of sulfopropyl ether (SPE) derivative of β -CD to interact with naphthalene. Higher association constants were observed for the SPE3- β -CD ($K = 2100 \text{ M}^{-1}$) and SPE5- β -CD ($K = 1800 \text{ M}^{-1}$) than were observed for β -CD ($K = 730 \text{ M}^{-1}$). Similar results were observed for the undecylsulfated methyl CD described by Menger and Williams (43). The lack of a steric hindrance by this highly substituted ionic derivative was explained through a "micellar" arrangement of the ionic substituents. The derivative was described as a "micellar" CD because the long hydrophobic alkyl groups in the substituent are expected to align themselves to reduce interactions with the

aqueous environment similar to micelle formation. The anionic charge at the end of the alkyl chain is expected to repel adjacent substituents effectively maintaining an opening to the CD cavity. Although the substituents are long enough to bend into the cavity, this is not expected due to the hydrophilic character of the ionic sulfate, which would prefer to interact with the aqueous solvent. The

**Fig. 6** Effect of changing the DS of 2HP- β -CD on its solubility (O) and the association constant (Δ) with phenolphthalein. (From Ref. 41.)

Fig. 7 Comparison of the binding constants of hydrophobic steroids, testosterone, and progesterone with β -CD and anionic β -CD derivatives. SA: Sulfonate anion at the 6-position, SPE: Anionic sulfopropyl ether substituent; and SBE: Anionic sulfobutyl ether substituent. (Adapted from Ref. 6.)

authors suggested the interaction of naphthalene occurred with the hydrophobic “arms” of the side chain and not the CD cavity although interaction with the cavity was not ruled out.

The sulfopropyl and sulfobutyl ether derivatives (44) have been further evaluated for their complexation with testosterone and progesterone (Fig. 7). Even though increasing the DS should produce more steric hindrance to complexation, the mono, tetra, and hepta substituted sulfobutyl ether (SBE1, 4, 7) derivatives all displayed comparable binding abilities for the steroids and the strength of binding was similar to that observed for β -CD. The SBE substituent behaves similar to that proposed for the undecyl sulfate CD, however, complexation with the SBE- β -CDs involves the CD cavity, as well as the hydrophobic butyl side arms.

Electronic effects

Effect of proximity of charge to CD cavity: The ionic derivatives that have charges closest to the CD cavity are the carboxylate, sulfate, and sulfonate derivatives. The complexation characteristics of the directly carboxylated CDs, C- β -CDs have not been reported but the highly anionic sulfated CD derivative (S14- β -CD) does not appear to form inclusion complexes (45). This may be either due to steric effects from the 14 sulfate substituents or due to the ionic state of the CD.

The effects of charge proximity on CD complexation behavior were evaluated (Fig. 7) by studying the complexation of two steroids by the sulfonate, sulfopropyl ether (SPE), and sulfobutyl ether (SBE) derivative (44). Electronic effects seem to be more of a factor than steric effects because even when only one sulfonate substituent is attached at the 6-position, (6-SA1- β -CD) the derivative

loses its complexation capability. The binding constant for testosterone is only 64 M^{-1} for 6-SA1- β -CD versus $17,800\text{ M}^{-1}$ for the neutral β -CD. The attachment of a single negative charge close to the CD cavity appears to disrupt the thermodynamics driving the complexation.

When one sulfonate ion (SA1) is directly attached to the CD, there is a minimal binding of the steroids but as the charge is spaced away by the three carbon propyl (SPE1) or a four carbon butyl group (SBE1), the derivatives regain the binding capability of the β -CD molecule. The monosubstituted sulfopropyl and sulfobutyl derivatives (SPE1 and SBE1) are able to bind progesterone and testosterone as well as β -CD. This suggests that ionic substituents too close to the CD cavity adversely disrupt the thermodynamics driving the inclusion complexation. Moving the charge away from the cavity re-establishes the complexation characteristics but this is dependent on the charge density in the structure.

Effect of charge density: As the charge density increases in the sulfopropyl family from a mono to a tetra and hepta anion, the binding of the steroids decreases. However, when the sulfonate anion was spaced four methylene units away, the charge density did not adversely affect the binding of the steroids. The mono, tetra, and hepta substituted sulfobutyl ether derivatives all displayed comparable binding abilities for the steroids and the strength of binding was similar to that observed for β -CD.

Effect of charge state of CD and drug: Ionic CDs are capable of complexing neutral hydrophobic drugs, if the ionic charge is not directly attached to the carbohydrate backbone of the CD. The trianion of CM3- β -CD (25) is able to complex a neutral drug, hydrocortisone with an association constant that is 74% of that observed for neutral β -CD. Although this anionic derivative is less effective than the neutral β -CD, a more favorable situation has been observed for the interaction of anionic SBE- β -CDs and neutral drugs. Okimoto et al. (46) reported that the anionic SBE- β -CD (Table 4) often exhibits 1:1 binding constants with neutral drugs that are comparable to or better than those observed for the neutral HP- β -CD. The better binding may be due to the butyl “micellar” arms extending the hydrophobic cavity of the CD.

When the drug and the CD are both charged, electrostatic effects may be observed. Adverse electronic effects have been observed for the complexation between the anionic form of indomethacin and the dianion of carboxymethyl- β -CD, CM2- β -CD (38). At pH 6.6, indomethacin exists as an anion and under these conditions, the anionic carboxymethyl CD did not complex the drug at all, probably due to electrostatic

(Adapted from Ref. 6.)

repulsions. However, the tri-anion, CM3- β -CD (25) has been reported to complex the anionic forms of warfarin and indomethacin (Table 5) although only at 71 and 60% of the binding observed for the neutral β -CD.

Experience with the carboxymethyl derivatives suggested the position of the charge in the drug structure may affect the interaction with an anionic CD. The spacing of the charge by the butyl group in the SBE substituent appears to lessen these repulsive effects observed for the

shorter carboxymethyl substituent. The binding constants between the anionic forms of indomethacin, and naproxen and the anionic SBE- β -CD (Table 4) are almost equivalent to those observed for the neutral HP- β -CD. The binding constant between SBE- β -CD and the anionic warfarin molecule, however, is much lower than that with HP- β -CD, suggesting that the position of the charge in the drug and how this interacts with the charge in the CD may be important.

Table 5 Effect of charge state of drug on binding to neutral β -CD and anionic carboxymethyl- β -CD

Hydrocortisone	Neutral	6200	4600
Indomethacin	Anionic	620	250
Warfarin	Anionic	520	150
Propranolol	Cationic	220	400

(Adapted from Ref. 25.)

Cooperative electrostatic interaction between the cationic drugs and the anionic CDs have been observed. Enhanced complexation is observed for the complexation of the cationic form of propranolol with the anionic CM3- β -CD (Table 5) and is probably due to cooperative electrostatic interactions. Similar positive interactions are observed with the SBE- β -CD and the cationic forms of cinnarizine, miconazole, papaverine, and thiabendazole (Table 4).

One difference in complexation performance of ionic versus neutral CDs is in their inability to participate in 1:2 or 1:3 complexations. The ionically charged CDs do not effectively form higher order complexes probably due to electrostatic repulsions between the first CD to sequester the drug and the incoming ionic CD. As the charge density increases, this repulsive effect is magnified. Rajewski et al. (50) demonstrated that as the charge density of the SBE- β -CD increases from one to four to seven, the solubilization of cholesterol decreases. Fortunately, the SBE-CDs are able to complex drugs effectively with the 1:1 complexation so the inability to effectively participate in 1:2 complexes does not impose any practical disadvantages.

Temperature, additives, and co-solvent effects

Inclusion complexation is an equilibrium process and the strength of association is affected by the temperature of the system. In most cases, as the temperature increases, the binding constant will decrease. For example, the binding constant for the neutral naproxen molecule (51) and β -CD decreased from 1379 to 975 to 778 M^{-1} as the temperature increased from 25°C to 35°C and 45°C, respectively. The solubility of a drug in the CD solution may increase with an increase in temperature even though the binding constant is decreasing because the increased

temperature improves the intrinsic solubility of the free drug (S_o in Fig. 5) (52, 53).

Organic solvents (54–56) typically reduce the complexation of a drug with CD by competing for the hydrophobic cavity. They also reduce the solubility of most CDs and their complexes. Recently, Loftsson et al. (57) and Redenti et al. (58) have reported on the use of water soluble polymers and hydroxy acids, respectively, to increase CD:drug complexation and improve the solubilizing effect.

Release from the Complex

Complexation of drugs by CDs improves their delivery characteristics and does not interfere with their activity because complexation is a rapidly reversible process. In aqueous solution, drug:CD complexes are continually forming and dissociating with lifetimes in the range of milliseconds or less (59, 60). Although slower kinetics of dissociation are seen with stronger binding, the rates are still fast and essentially instantaneous. After administration, the drug is released from the complex upon dilution, and in some cases with contributions from competitive displacement with endogenous lipophiles, binding to plasma and tissue components, drug uptake into tissues is not available to the complex, and rapid elimination of the CD (61).

The effects of dilution are demonstrated in Fig. 8 (62) for complexes with various binding constants. Most drug:CD complexes exhibit binding constants in the range of 100–20,000 M^{-1} and Fig. 8 demonstrates that even for the more tightly bound drugs, a 1:100 dilution will reduce the percentage of drug complexed from 100% to 30%. A 1:100 dilution is readily attained for

Fig. 8 Correlation between percentage of complexed drug and CD concentration at various K values. (Adapted from Ref. 62.)

intravenous products and upon dilution in the stomach and intestinal contents.

Dilution is minimal, however, when drugs are administered via routes such as ophthalmic, transmucosal, and transdermal. Under these conditions, the drug can still be displaced from the CD cavity by competing lipophiles such as triglycerides, cholesterol, bile salts, and other hydrophobic compounds often found in high concentrations at the site of delivery.

BENEFITS OF COMPLEXATION

Improvement in Solubility, Dissolution, and Bioavailability

CD formulations provide improved aqueous solubility to poorly soluble drugs, and the drug:CD complex often exhibits improved dissolution characteristics compared to other formulations of the drug. These two features can provide for an improvement in oral bioavailability when solubility and the rate of dissolution are limiting the availability of the drug for absorption. For example, the drug cefotiam hexetil hydrochloride forms a gel under the acidic conditions of the gastric contents and shows poor dissolution. A variety of excipients were screened to prevent gelation and α -CD complexation afforded the best formulation for the dissolution and solubilization of the drug (63).

Another example is the calcium channel blocker, cinnarizine. This drug exhibits a very low and erratic bioavailability after oral administration as a suspension ($F = 8 \pm 4\%$) or capsule ($F = 0.8 \pm 0.4\%$). When it was administered as a complex with SBE4- β -CD or HP- β -CD (64), either as a solution ($F = 55\text{--}60\%$) or in a capsule ($F = 38 \pm 12\%$), the bioavailability was significantly enhanced. The improvement in bioavailability was attributed to enhanced dissolution and solubilization via the complexation.

A review of the literature reveals several hundred citations and reviews that describe the effects of complexation on dissolution and bioavailability of drugs. A broad range of CD and CD derivatives have been investigated as well as many different drugs. Some other representative examples are spironolactone (65), meclizine (66), ketoprofen (67), oxazepam (68), danazol (69), phenytoin (70), and tolbutamide (71). Although these studies demonstrate the general application of complexation for improvements in dissolution and bioavailability, the use of complexation may not be practical for some dosage forms due to the amount of CDs required. β -CD for example has a molecular weight of 1135. If one uses a

mole ratio of 5:1 to promote solubility, then over 350 mg of CD will be required for a 25 mg dose of a drug having a molecular weight of 400. This can limit the type and dose of drug that can realistically be used with complexing agents for solid oral dosage forms.

Solution formulations, however, do not typically have these same constraints, and complexation provides an alternative to the use of non-aqueous solvents or large volumes. A few derivatized CDs (e.g. hydroxypropyl and sulfobutyl ether) can be safely administered by parenteral routes. This is often where complexation and its improvements in aqueous solubility can be most readily utilized. The derivatized CDs often can be used to replace cosolvents such as ethanol, polyethylene glycol, and lipids, as well as provide an alternative to the use of emulsions and liposomes. The hydroxypropyl and sulfobutyl ether derivatives are stable in solution and can be readily autoclaved, often improving the heat stability of drugs. There are however, reports of complexation of CDs with anti-oxidants (72) and preservatives (73, 74) with both decreased and increased efficacy (75).

Reduction of Unpleasant Side Effects and Bitter Taste

Improvements in the rate and extent of dissolution of a drug can improve the rate of absorption of the drug. Reducing the contact time between the drug and the tissue mucosa can help minimize tissue irritation produced by drugs. Nonsteroidal anti-inflammatory drugs cause a high incidence of gastrointestinal ulcerative lesions that are a result of both local irritation from the drug and systemic inhibition of prostaglandin synthesis by the drug. CD formulations of naproxen (76), diclofenac (77), and piroxicam (78) cause fewer gastric lesions associated with the acute local tissue irritation than produced by the drug alone. Formulations containing CDs have also shown less irritation than nonCD containing formulations for ophthalmic (79), intravenous (80), and intramuscular (81) administration, and in cellular injury screening tests (82).

Complexation with CDs can also have the effect of reducing the amount of contact with taste receptors. This can be of great benefit in the preparation of oral solutions. Not only are the drugs "masked" from the receptors by inclusion in the CD cavity, but the increased hydrophilicity enables the easier removal of the bitter substance from the receptor surface as well. The apparent concentration of the uncomplexed bitter drug is a function of the complexation constant, the amount of free CD, and the water solubility of the drug (83). Complexation has been used to mask the unpleasant bitter taste of a number of drugs such as oxyphenonium

bromide (84), propantheline bromide (85), clofibrate (86), and acetaminophen (83).

Improvements in Drug Stability

CDs are normally thought of as stabilizing agents in pharmaceutical formulations (87, 88). They have been shown to stabilize drugs to hydrolysis (89) and hydrolytic dehalogenation (90), oxidation (91), decarboxylation, and isomerization (92), both in solution and in the solid state. They can, however, accelerate these same reactions (93, 94). The nature of the stabilization or destabilization depends on the CD used (parent and functional groups of any derivative) and on the position of the guest molecule inside the CD. If the molecule is positioned such that the area of instability is located outside the CD, no effect on stability may be observed. When the position allows interaction of the CD hydroxyls (or derivative functional groups) with a hydrolytically prone site, decreased stability may be observed but if the site is located fully within the CD, enhanced stability usually results.

In the solid state, stabilization of drugs to degradation has been reported for numerous drug including nicardipine (95), colchicine (96), prostaglandin E₁ (97), diclofenac (98), and sulfamethoxazole (99).

Stabilization is not limited to small compounds, as larger molecules such as peptides and proteins can also form complexes that result in enhanced chemical and physical stability (100). The CDs will typically interact with functional groups present on exposed surfaces of the macromolecules and often form multiple complexes (several CDs per molecule). Stabilization against aggregation has been observed for CD complexes in solution with proteins such as ovalbumin and lysozyme (101), carbonic anhydrase (102), and insulin (103), and in the solid state with albumin and gamma-globulin (104). CD complexes have also been investigated as chaperone-mimics (105) in the refolding of denatured proteins (106).

The degree of stabilization/destabilization of a drug complexing with a CD depends not only on the rate of degradation within the complex, but also on the fraction of drug that is complexed (88), and the stoichiometry (107). Increased stability is often observed for compounds having high association constants and those that tend to form higher order complexes.

Reduction in Volatility

Inclusion complexes have been prepared with a number of volatile substances (108, 109) including spices, flavors,

essential oils, and several drugs. CD complexation has been shown to reduce the volatility and improve the stability of many compounds. Examples include lemon oil (110) and other flavoring agents (109), clofibrate (86), isosorbide 5-mononitrate (111), and nitroglycerine (112). In addition, complexation facilitates the handling of products, particularly because they transform liquids to solids. The solid form can also provide certain formulation advantages over liquids such as eliminating the melting point and hardness reduction of suppositories commonly observed when liquids are added (113).

CYCLODEXTRINS

α -, β -, and γ -CDs

CDs, also called Schardinger dextrins, cycloglucans, or cycloamyloses, are α -1,4 linked cyclic oligosaccharides obtained from enzymatic conversion of starch. The parent or natural CDs contain 6, 7 or 8 glucopyranose units and are referred to as alpha-(α -CD), beta-(β -CD), and gamma-(γ -CD) CD, respectively. The chemical structure of β -CD (Fig. 2) shows the cyclic nature of the molecule,

Table 6 Characteristics of α -, β -, and γ -CDs

(Adapted from Ref. 7.)

and the presence of three hydroxyl groups on each glucopyranose unit. Two of the hydroxyls are secondary alcohols and are located at the C-2 and C-3 positions of the glucopyranose unit. The third hydroxyl is a primary alcohol at the C-6 position. The hydroxyls provide the hydrophilic exterior responsible for the aqueous solubility (Table 6) of the CDs.

In three dimensions, this structure forms a truncated cone where the primary hydroxyl groups are located on one face and the secondary hydroxyl groups on the other. The interior of the cone is hydrophobic due to the presence of the glycosidic ether oxygens at O-4 and the hydrogens attached to C-3 and C-5, and thereby provides a cavity for the inclusion of hydrophobic compounds. The cavity varies in size with α -CD being the smallest at about 5.3 Å across and γ -CD the largest at 8.3 Å diameter (Table 6).

Properties in solution

The solubilities of the natural CDs in water varies and is quite dependent on temperature (Table 6). The unusually low water solubility of β -CD is due to the very rigid structure that results from the H-bonding of the C-2 hydroxyl of one glucopyranose unit with the C-3 hydroxyl of an adjacent unit (114). In the β -CD molecule, a complete set of seven intramolecular H-bonds can form, effectively limiting interactions with the solvent. This "belt of H-bonds" is incomplete in the other parent CDs thus allowing more favorable interactions between α - and γ -CD and water molecules. This is consistent with the observation of a less favorable enthalpy and entropy of dissolution (115) for β -CD versus α - and γ -CD. Recent studies have suggested that the abnormally low water solubility of β -CD may be exacerbated by aggregation of these rigid β -CD molecules (116). The solubility of β -CD can be increased by disrupting this aggregation through the addition of solvent structure-altering substances such as urea (117), inorganic salts (118), and hydrophilic polymers (119).

Solubility of the CDs is low in most organic solvents (Table 6). In aqueous/organic cosolvent systems, the solubility decreases as the organic concentration increases, with the exceptions of ethyl and propyl alcohol where a maximum is observed at around 30% alcohol (120).

In solution, the CDs are fairly stable to hydrolysis in alkaline medium. Under acidic conditions, the α -1, 4 glycosidic bonds are slowly broken to open the ring, and then to give glucose and a series of linear maltosaccharides. The initial opening of the ring is a slower process by about 2–5-fold than the subsequent hydrolysis of the linear dextrins. The initial ring-opening kinetics are the most important for pharmaceutical

Fig. 9 Water vapor sorption isotherms for α -, β -, and γ -CD at 40 °C. (Dashed line: adsorption, solid line: desorption). (Adapted from Ref. 7.)

preparations as complexation requires the intact cyclic structure. Half-lives for the ring opening reaction step at 70°C and 0.2 M HCl are 25.2, 14.5, and 7.1 h for α -, β -, and γ -CD, respectively (121). Additional pH/rate data are available in the literature (122).

Similar reaction products are observed with gamma-irradiation in solution (123), but in the crystalline solid state, the mechanism appears to be different and no glucose is formed.

Solid state properties

The three natural CDs form crystalline structures in the solid state that decompose above 200°C with no definite melting points. They are not considered hygroscopic, but they do form various stable hydrates. The water vapor sorption isotherms (Fig. 9) show two phases for the β - and γ -CDs, and one phase for α -CD. At 11% RH, α -CD absorbs 4 water molecules and upon long-term storage, forms a stable hydrate with 6 water molecules. The water content gradually increases with increasing humidity to a constant value of 6.6 water molecules per CD molecule at and above 79% RH (124). Four different crystalline forms of α -CD have been reported; two forms containing approximately 6 water molecules, one form containing 7.6 water molecules and a dehydrated form.

The water content of β -CD increases with increasing humidity and passes through a plateau region at about 23–31% RH where the water content is about 5–6

water molecules. Another leveling of the plot occurs at humidities of 60–79%. Both 12-water (125) and 11-water (126) hydrated crystalline forms have been reported along with a dehydrated form. Upon standing for several weeks, the 11-water form will convert to the 12-water form, which is stable over a large range of humidity conditions.

X-ray diffraction patterns of γ -CD stored under various humidity conditions also show the existence of three distinct crystalline forms. A dehydrated form is observed at low humidities and a hydrated form containing almost 17 water molecules occurs at 93.6% RH. An intermediate crystalline form containing 7 water molecules is found at intermediate RH values which corresponds to the plateau region at 20–30% RH in the sorption isotherm. The hydrate and dehydrate forms pass through the intermediate form during dehydration, and hydration respectively (124).

CD Derivatives

Hundreds of modified CDs have been prepared and shown to have research applications. However, only the derivatives containing the hydroxypropyl (HP), methyl (M), and sulfobutyl ether (SBE) substituents are in a position to be used commercially as new pharmaceutical excipients. These substituents vary in size and electronic character and are attached to the CD structure through reaction with one or more of the three hydroxyl groups of the glucopyranose units. The parent CDs contain 18 (α -CD), 21 (β -CD), or 24 (γ -CD) hydroxyl groups that are available for modification. The most reactive hydroxyls are in the C-6 position and the C-3 hydroxyls are the least reactive. However, the difference in reactivity is not great, and changing reaction conditions can often alter the position of substitution. The preparation of homogenous, selectively derivatized CDs is, therefore, not an easy task. With all the options available for positional and regioisomers to be formed, one must be careful in describing the various derivatives. A discussion of nomenclature is provided earlier.

The main derivatives under development as excipients are all derivatives of β -CD: 1) A randomly methylated derivative with an average MS of 14 (M14- β -CD), 2) Two different 2-hydroxypropyl derivatives, one with an average MS of approximately 3 ((2HP)3- β -CD) and the other with an average MS of 7 ((2HP)7- β -CD), and 3) A sulfobutyl ether derivative with an average MS of 7 (SBE7- β -CD). Glucosyl and maltosyl CDs (127, 128) which contain a mono- (G_1 - β -CD) or disaccharide (G_2 - β -CD) substituent, have also been reported and show promise for the future.

Methylated

Methylation can be controlled to produce mono- to fully derivatized CDs. The introduction of the methyl substituent dramatically improves the water solubility of the derivative versus the parent CD. Aqueous solubility increases as the number of methyl groups reaches 14 and then decreases as substitution approaches 21. The 2,6-DM14- β -CD and the 2,3,6-TM21- β -CD have solubilities of 57 and 31 g/100 ml, respectively, versus 1.8 g/100 ml for the parent β -CD. The introduction of the methyl groups disrupts the “belt of H-bonds” effectively increasing the polarity of the derivative.

The aqueous solubility of these derivatives is adversely affected by temperature, however, and precipitation occurs during heat sterilization. The mixture of randomly methylated β -CD (M14- β -CD) (129), however, exhibits a favorable water solubility (>50 g/100 ml) that increases as temperature increases (130).

The extent of methylation is also important in optimizing complexation. The introduction of the methyl substituent at the 2- and 6- positions appears to improve complexation. Binding constants for 2,6-DM14- β -CD with many drugs is an average five times of that observed with β -CD. The methyl groups seem to increase the hydrophobicity of the CD cavity possibly by providing an “extension” of the cavity. Derivatization of the remaining C3 hydroxyls, however, results in a dramatic decrease in complexation ability. This may result from the distorted cyclic structure formed when the CDs are permethylated (131). The altered conformation also impacts the stability of the derivative in acidic solutions. Degradation half-lives of 2.1 and 12.0 h have been reported for a randomly methylated (2, 3, 6) M14- β -CD and a 2,6-DM- β -CD, respectively, in 1 M HCl at 60°C (129). Under similar conditions, β -CD has a half-life of 5.4 h.

The mixture of randomly methylated β -CD, although partially derivatized at the 3-position, still maintains the favorable binding characteristics of 2,6-DM14- β -CD. One report (129) demonstrated that M14- β -CD solubilized 26 drugs more effectively than β -CD and the extent of solubilization was on average 80% of that observed for the purified 2,6-DM- β -CD preparation.

Studies suggest that an optimal definition for a commercially viable methylated CD is the partially methylated β -CD (M14- β -CD) containing an average MS of approximately 14 with the substituents at the 2-, 3-, and 6-positions. This material is produced economically, has an aqueous solubility that increases with temperature, and has binding constants higher than those observed with the unsubstituted β -CD and close to those observed with the 2,6-DM- β -CD.

Hydroxypropyl

Hydroxy alkylation of β -CD requires treating base-solubilized β -CD with the appropriate epoxide or haloalcohol (132, 133). Propylene oxide or propylene carbonate are used in the preparation of 2-hydroxypropyl β -CD ((2HP)- β -CD), the derivative being commercialized. The reaction occurs at both primary and secondary alcohols on the β -CD generating a mixture of numerous isomeric forms (134, 135). This results in a heterogeneous product that is amorphous and highly water soluble.

The 2-hydroxypropyl derivative has been the subject of numerous clinical trials and is commercially available from several suppliers. Brandt (136), Müller (137, 138), and Pitha (139) have described its preparation and use. The DS can affect the ability of the hydroxypropyl derivatives to form complexes. It can also affect the solubility of the derivatives. The mono substituted derivative, (2HP)1- β -CD is actually less soluble than β -CD (140). However, at degrees of substitution of ~ 2.7 and higher, the solids are amorphous and exhibit solubilities in excess of 50% w/v (135). Water uptake by the solid forms is low. At 75% RH and 25°C, the (2HP)- β -CDs show less water uptake than the parent β -CD (135), and the water uptake decreases with increasing MS.

As discussed earlier, the need to control the DS becomes important to balance water solubility and complexation capability. Two commercial preparations of (2HP)- β -CD, EncapsinTM and Molecusol[®], have recognized the need for this compromise and have substitution levels that provide a balance between solubility and complexation. Encapsin and Molecusol have MS values of approximately 3 and 7, respectively. Although both (2HP)- β -CD commercial preparations are unique, each manufacture can reproducibly generate materials to meet defined specifications. These (2HP)- β -CD derivatives appear to be equally effective in complexation and have water solubilities exceeding 50% w/v. Both have been administered parenterally.

Sulfobutyl ether

Rajewski (48) prepared the directly sulfonated CDs through the introduction of the sulfonic acid moiety at the C-6 position. These anionically charged sulfonic acid substituents were spaced away from the CD with alkyl groups by Parmeter (141) and Lammers (142) in the preparation of sulfopropyl derivatives of CDs.

Stella and Rajewski (44) later described the preparation of sulfoethyl through sulfohexyl derivatives of the CDs. The sulfonate and sulfoalkyl ether derivatives can be prepared with different average

degrees of substitution (143), are isolated as the sodium salts, and demonstrate water solubilities independent of the MS. Likewise, no effect on complexation is seen with changes in MS when the alkyl spacer is butyl (Fig. 7). The SBE- β -CD derivatives are amorphous and similar to HP- β -CDs, tend to form amorphous complexes. They are highly water soluble (>50 mg/ml), and somewhat hygroscopic, reversibly picking up water at humidities below RH 60%.

The SBE7- β -CD derivative has been used in clinical trials and is being developed commercially as Captisol. It is well characterized and suitable for parenteral administration.

ABSORPTION, DISTRIBUTION, METABOLISM, AND EXCRETION

Oral Pharmacokinetics

The parent CDs are poorly absorbed from the gastrointestinal tract. Reported values for absorption range from 0.1 to 0.3% (144) for rats fed a diet containing 5–10% β -CD, to $\sim 2\%$ (145) when the doses were administered in an isolated rat ileum closed-loop experiment. When ^{14}C β -CD was administered orally, values as high as 4.8% have been reported for appearance of the label in the urine (146). This higher value was attributed to absorption of the metabolites of β -CD. The small amount of intact CDs absorbed orally probably does so by passive means (147), via the paracellular route (148). Oral absorption studies with α - and γ -CD have shown $\leq 2\%$ and $\leq 0.1\%$ absorption, respectively (149, 150).

The majority of an orally administered dose of α - and β -CD will be metabolized in the colon. This has been demonstrated both in rats (146) and man (151) with very little hydrolysis occurring in the upper gastrointestinal tract (GIT). Microbiological studies (152) have shown that most of the human colonic bacterial strains can degrade α - and β -CD and this activity can be stimulated by as little as 2–4 h of exposure to the CDs. The typical 40 h transit time through the human colon provides adequate time to induce the bacterial enzymes to provide for complete hydrolysis of the CDs in the colon. Likewise, most of an oral dose of γ -CD is metabolized in the GIT. However, studies with radiolabelled γ -CD suggest that most of its metabolism occurs in the upper GIT (153).

The derivatized CDs are generally more resistant to hydrolysis in the GIT than the parent CDs. Oral bioavailability of HP- β -CD in dogs is estimated at 3.3% and is less in rats, and about 60% of the dose is excreted

Table 7 Pharmacokinetic parameters for several CDs

unchanged (154). Oral absorption in humans has not been observed (150). Oral administration of ^{14}C HP- β -CD to rats results in approximately 3% of the radiolabel appearing in the urine, 71% in the feces, and 3% being exhaled (155).

The methylated derivatives have shown somewhat greater oral absorption. The absorption of DM- β -CD has been reported as 6.3–9.6% in the rat (156), and M- β -CD as 0.5–11.5% (153).

Parenteral Pharmacokinetics

Intravenously administered CDs disappear rapidly from the systemic circulation and are excreted mainly through the kidney. α - and β -CD are excreted almost completely in their intact form, but some metabolism is observed with γ -CD. Reports vary with regard to the amount of metabolism from “substantial” (157) to 10% or less (153). The hydrophilic CD derivatives are likewise rapidly cleared following intravenous administration and most are excreted unchanged in the urine. Linear, two compartment pharmacokinetics are usually observed although the initial distribution kinetics are very rapid and may not always be captured.

The disposition parameters for several CDs are given in Table 7. The steady state volumes of distribution (Vd_{ss}) correspond well with extracellular fluid volume in each species evaluated, suggesting little or no distribution of most CDs into other tissues or storage compartments.

Studies with ^{14}C HP- β -CD have shown that the small amount that does distribute, has been found mainly in the kidney and lungs of rats following single intravenous doses, and in the kidney and liver of dogs after chronic (1 month) intravenous dosing (154). The total plasma clearances (CL_T) are dose independent and are indicative of clearance at a rate comparable to glomerular filtration (158, 160). Thus, as with any compound whose elimination is closely tied to kidney function, linear pharmacokinetics may not always be observed in the presence of poor renal function.

SAFETY OF CD

Oral Safety

The oral safety of the parent β -CD was first reported in 1957, and it was erroneously suggested that the material was unsafe (162). Subsequent studies by Anderson et al. (163) and Gerlóczy (164) demonstrated that α - and β -CD produced no toxic effects when fed to rats for 30–90 days at 1% of the diet or at 1 and 2 g/kg daily doses. The odd, irreproducible results of the first report were probably due to the inconsistent purity of early CD materials and the possible presence of residual organic solvents.

Both rodent and nonrodent studies have been conducted on the parent CDs. Szejtli and Sebestyén (165) reported the parent CDs to be nontoxic at very high oral doses. Mortality was not observed, even in animals treated with

the highest possible oral doses. Therefore, the LD₅₀ in rats is reported to be greater than 12.5, 18.8, and 8 g/kg body weight for α -, β -, and γ -CD, respectively.

In general, the oral administration of α -, β -, and γ -CD appears to cause several changes reflective of an adaptation to a diet containing a poorly digestible carbohydrate. The changes are species dependent, with rats being more susceptible than dogs. In both cases, the effects are reversible upon cessation of treatment.

α -, β -, and γ -CD

The safety of orally administered β -CD has been investigated in numerous studies (120, 144, 166, 167) with extensive evaluation of hematology, blood chemistry, urinalysis, and necropsy (macro and microscopic). No significant toxic effects were observed in any of these studies after oral administration of β -CD to mice, rats, or dogs.

Although no macroscopic pathologies were observed, microscopic evaluation of the tissues revealed several treatment-related changes from the 1-year exposure of rats to β -CD (167). The organs affected by the treatment were the kidneys and the liver. The kidney effects were not thought to be of any toxicological importance.

Some cellular necrosis was observed in the liver of male rats receiving a 5% β -CD diet and in female rats receiving a 2.5 and 5.0% β -CD diet. An increase in portal inflammatory cell infiltration was also observed in male rats receiving the 2.5% β -CD diet and male and female rats receiving the 5.0% β -CD diet. These observations were considered to represent a mild hepatotoxicity (mechanism unknown), which was further evidenced by increases in serum liver enzymes.

The 1-year exposure (167) of dogs to β -CD diets did not result in the kidney or liver pathologies observed in the rats. Therefore, the mild hepatotoxicity may be species related and not reflective of a general hepatotoxicity. Dogs fed 5% β -CD for 1 year exhibited increased urinary protein levels and the urinary excretion of calcium. However, these changes were not noted in the rat study.

From the results of the 1-year studies, the nontoxic effect levels for oral use of β -CD are considered to be 1.25% of the diet for rats and 5% for dogs. Considering the quantity of food that was consumed under these conditions, this is equivalent to approximately 760 and 1899 mg/kg/day for rats and dogs, respectively.

α - and γ -CD show similar oral safety profiles to those observed for β -CD. Ninety-day feeding studies in rats and dogs (153) consuming diets containing α -CD or γ -CD have shown effects that are consistent with the consumption of a poorly digestible carbohydrate such as β -CD or lactose. Some increases in organ weights (spleen and male

adrenals) have been observed but were reversible. The ingestion of γ -CD for 13 weeks at dietary levels of up to 20% (corresponding to intakes of 11.4 and 12.7 g/kg body weight/day for male and female rats, respectively) has been shown to be well tolerated (168).

The treatment of dogs with 0, 5, 10, and 20% α -CD and γ -CD diets resulted in minimal effects as compared to those observed in rats (153). A subsequent study concluded that daily γ -CD consumption of up to 20% in the diet (approximately 7.7 g/kg body weight in male and 8.3 g/kg body weight in female dogs) is tolerated without any toxic effects (169).

CD derivatives

Oral safety studies have been conducted with at least two derivatives, the HP3- β -CD and SBE7- β -CD. The reported studies for these derivatives are listed in Table 8. The oral safety of HP3- β -CD has been assessed in mice, rats, and dogs for dosing periods up to 2, 2, and 1 year, respectively. Doses reached as high as 5000 mg/kg/day. No adverse effects were noted except for an increase in diarrhea in dogs treated with 5000 mg/kg. The 2-year carcinogenicity studies are discussed separately later.

The oral safety of SBE7- β -CD derivative is currently under evaluation.

Parenteral Safety

The most encompassing test of an excipient's safety is the systemic safety of the material because many of the routes of administration ultimately result in at least some minor systemic exposure. Numerous studies with the parent CDs have shown that their parenteral toxicity is observed primarily as renal and cytotoxicity (hemolysis and tissue

irritation). These toxicities were the driving force for the preparation of new CD derivatives, many of which exhibit improved parenteral safety.

α -, β -, and γ -CD

Renal issues: The parent CDs can all show a toxic effect on the kidney when given parenterally. The nephrotoxicity of α - and β -CD manifests itself as a series of alterations in the organelles of the proximal tubule cells (170). The toxicity is initially expressed as an increase in apical vacuoles, which is typical of an adaptive response to the excretion of osmotic agents at extremely high concentrations. This effect reverses upon discontinuation of CD administration. However, there are also other cellular changes not typical of osmotic agents that are not reversible. Giant lysosomes appear and prominent acicular (needle-like) microcrystals are observed in the epithelial cells of the renal proximal tubules. Both the occurrence and abundance of the microcrystals are dose dependent. The content of the crystals has not been confirmed but suggestions include precipitated parent CD (unlikely for α -CD with a solubility of 145 mg/ml), and complexes of CDs with cholesterol (171) or lipoproteins (172). The proximal tubules progressively show dramatic alterations in other organelles. The mitochondria are observed to swell and become distorted. The Golgi apparatus is affected along with the smooth endoplasmic reticulum. The interstitial membrane on the basal lateral side of the cell is disrupted. All of these events are irreversible, and as the toxic condition progresses, kidney function is lost and death ensues.

Parenterally administered γ -CD appears to be less nephrotoxic than α - or β -CD. Subcutaneous and intravenous doses as high as 4000 mg/kg in mice and 2400 mg/kg in rats have shown no toxic effects (173). Schmid (174) reported that the intravenous LD₅₀ for γ -CD in mice was 10,000 mg/kg and >3750 mg/kg for rats. For acute intravenous administration, γ -CD has been shown to be safer than α - and β -CD, which exhibit LD₅₀ values of 1000 and 788 mg/kg, respectively, in the rat (170, 174). Antlisperger (153), and more recently Donaubaue (175), evaluated the intravenous administration of γ -CD to rats for 30 and 90 days. A no adverse effect level (NOAEL) of 200 mg/kg was reported for the 30-day studies and 120 mg/kg was suggested for the 90-day studies.

Cytotoxicity issues: In-vivo hemolysis has been observed with parenteral administration of all of the parent CDs. In-vitro studies with human erythrocytes have demonstrated that the damaging effect of the CDs is in the order β -CD > α -CD > γ -CD (176). This cellular destruction has also been observed in studies with human skin fibroblasts and intestinal cells (177), P388

murine leukaemic cells (178), *E. coli* bacterial cells (179), and immortalized human corneal epithelial cells (180). Mechanistic studies suggest that CDs extract either cholesterol (β -CD and γ -CD) or phospholipids (α -CD) from the cell membrane causing small pores which allow leakage and eventually lead to cell lysis.

These in vitro cytotoxicity studies are not indicative of in vivo toxicity but rather provide a method to classify the CDs for their potential to destabilize or disrupt cellular membranes. In fact, when whole blood is used instead of erythrocytes for the hemolysis tests, the cytotoxicity of the CDs is diminished 10-fold by the presence of hydrophobic serum components. Thus, the membrane damaging effects of the CDs are observed in vivo only under situations of high concentrations.

CD derivatives

Renal issues: The derivatized CDs vary widely in their potential for renal safety. Renal nephrosis was observed for methylated β -CDs following intramuscular injections of as little as 50 mg/kg/day over 12 days (181). The damaging effect of the methylated CDs was in the order of TM- β -CD > M- β -CD > DM- β -CD > β -CD. An LD₅₀ value of 220 mg/kg has been reported for DM- β -CD (159). Administration of the maltosyl/dimaltosyl derivatives G₂- β -CD/(G₂)₂- β -CD on the other hand, showed no toxic effects on the kidney of rats at intravenous doses of 200 mg/kg for 14 days (182). There was however, a flushing of the eyes, nose, mouth and extremities observed, prompting additional investigation.

Safety of the hydroxypropyl and sulfobutyl ether derivatives has been studied in considerable detail and little or no renal toxicity has been demonstrated at moderate doses. Summaries of available intravenous safety studies are given in Table 9. Parenteral exposure with either derivative results in the osmotic adaptive response seen with β -CD but further progression to the irreversible damage does not occur.

Ninety-day intravenous dosing of (2HP)3- β -CD at 400 mg/kg resulted in moderate toxicity as evidenced by decreases in body weight gains, changes in blood and serum parameters, increased activity of mononuclear phagocytosing cells of the lungs and liver, and an increase in the red pulp hyperplasia in the spleen (183).

The evaluation of the sulfobutyl ether derivative, SBE7- β -CD for 6 months with daily intravenous dosing up to 600 mg/kg did not present evidence of the effects noted with (2HP)3- β -CD and demonstrates the extensive systemic safety of this CD.

Cytotoxicity issues: As with renal toxicity, the various derivatives show dramatically different hemolytic behaviors. The dimethyl derivative shows substantial

hemolysis; more than even the parent β -CD. This is well illustrated in Fig. 10 where the percentage of cells undergoing hemolysis is shown as a function of CD concentration. Hemolysis started at concentrations below 0.1% for the DM- β -CD. Four to five times higher concentrations of β -CD are required to give the same hemolysis. This behavior is in agreement with the demonstration of DM- β -CD as a penetration enhancer in skin (184) and nasal tissue (185).

The hydroxypropyl and sulfobutyl ether derivatives, on the contrary, show much less hemolysis than β -CD. This is shown in Fig. 11 where the hemolysis caused by β -CD is compared to two (2HP)- β -CDs and three SBE- β -CDs (186). The hemolysis profiles show a dependence on the MS for the derivatives, showing less effect with higher MS. The two hydroxypropyl derivatives, (2HP)3- β -CD and (2HP)7- β -CD, are almost equivalent in their hemolytic behavior and are both less hemolytic than

Fig. 10 Hemolytic effects of CD derivatives on human erythrocytes in isotonic phosphate buffer (pH 7.4) at 37 °C for 30 minutes. (Δ , α -CD; \circ , β -CD; \square , γ -CD; \blacksquare , DM- β -CD; \blacktriangle , HP- β -CD; \bullet , HE- β -CD.) (Reprinted from Ref. 135.)

β -CD. Likewise, the sulfobutyl ether derivatives are less hemolytic than β -CD, but the effect of MS is quite dramatic. As the MS increases from one to four to seven, the hemolytic activity drops precipitously to where essentially no hemolysis is observed with SBE7- β -CD.

Mutagenicity and Carcinogenicity

The potential for interaction with genetic material (and therefore risk of carcinogenicity) can be investigated using bacterial and mammalian gene mutation assays and

Fig. 11 Hemolytic effects of CD derivatives on human erythrocytes in isotonic phosphate buffer (pH 7.4) at 37 °C for 5 minutes. \blacksquare , β -CD; \square , SBE1- β -CD; \bullet , (2HP)3- β -CD; \blacktriangle , (2HP)7- β -CD; \triangle , SBE4- β -CD; \circ , SBE7- β -CD. (Adapted from Ref. 186.)

chromosomal aberration assays. The parent CDs do not exhibit mutagenic behavior in any of these assays (153, 165), and there have been no reports of tumors in oral feeding studies or in the parenteral administration of any of the parent CDs.

Several of the CD derivatives have also been evaluated for mutagenicity and carcinogenicity. Both HP- β -CD (187, 188) and SBE7- β -CD (189) show negative results for the mutagenicity tests. However, a 2-year carcinogenicity study of HP- β -CD in rats demonstrated hyperplastic and neoplastic changes in the acinar cells of the exocrine pancreas (190). The neoplasia in the rat study is inconsistent with the mutagenicity assay results and with the lack of carcinogenicity of the parent CDs. In separate and shorter studies with mice and dogs, no adverse effects were observed for the pancreas.

The rat pancreatic hyperplasia may be due to the ability of high concentration of HP- β -CD to increase the fecal elimination of bile salts indirectly causing a stimulation of the production of cholecystokinin (CCK). In the rats, CCK functions as a mitogen causing an increase in the cellular hyperplasia in the acinar cells. Sensitivity to this effect is species dependent (191), the rat is most sensitive and dog show no effects. The carcinogenicity study for HP- β -CD may have been conducted at levels that are affecting an important nutritional balance. The FDA guidelines for carcinogenicity studies suggest that safety studies be conducted with the highest levels possible to determine maximum tolerated doses but care should be taken to minimize possible nutritional deficiencies (192). The observation of pancreatic neoplasms observed with the 5 g/kg/day oral doses of HP- β -CD may have been the consequence of a nutritional deficiency not a carcinogenic effect of HP- β -CD itself.

Reproductive Safety

In oral-safety studies involving both male and female animals, some minor differences were observed between the sexes. The parent CDs, however, do not adversely affect either gender and the effect of CDs on reproduction is minimal (166). Embryotoxicity and teratogenicity studies have been reported for α - and γ -CD (193). Several 90-day feeding studies in rats and rabbits have been conducted with no effects being observed for maternal health or reproduction (153).

A more extensive evaluation of reproductive and developmental safety of β -CD was reported in a three-generation study by Barrow et al. (194). The only adverse effect observed during the study was a dose related decrease in pup weight gain from birth until weaning but

this was statistically significant only for the 5% β -CD diet during days 7–14 postpartum. This preweaning growth retardation did not result in any permanent defects and the affected pups returned to normal weights upon weaning. The NOAEL for oral β -CD, under the conditions of the study, was suggested to be at 1.25% dietary β -CD.

Reproductive safety studies have been conducted for both SBE7- β -CD and HP3- β -CD in rats and rabbits. A listing of the reported studies is given in Table 10. Oral administration of up to 5000 mg/kg HP- β -CD to pregnant rats produced no maternal toxicity, embryotoxicity, or teratogenicity. Oral administration of 1000 mg/kg HP- β -CD to pregnant rabbits caused a slight maternal and embryotoxicity but no teratogenicity.

Intravenous administration of HP- β -CD at 400 mg/kg to the dams from day 18 of the pregnancy to 3 weeks of lactation produced no adverse effects on the rat pups. However, when the dosing occurred from day 16 of gestation to week 3 of lactation, the low dose (50 mg/kg) and the high dose (400 mg/kg) presented significantly lower pup survival than the vehicle control groups.

These effects were not observed with the intravenous administration of SBE7- β -CD at doses of 100, 600, and 3000 mg/kg to pregnant rats. There were no effects of intravenous treatment with SBE7- β -CD on fertility or early embryonic development, nor was the material observed to be teratogenic. The only effect of treatment was a decrease in maternal body weight gains and food consumption at the highest doses administered.

REGULATORY STATUS

Regulatory Process for New Excipients

CDs are not “standard” inactive ingredients, and their uncertain regulatory status causes hesitancy in their use in formulations. A common perception exists that an approval process is in place for the evaluation of new excipients, such as the CDs. In fact, there is no mechanism for submission and review of data on a new excipient that would lead to approval of that excipient. In the United States, the FDA reviews a new excipient only in relationship to the review of a drug formulation. Only the final drug product is approved by the FDA. By this method the excipient data are reviewed with each drug application. The dossier on a new excipient is filed by the excipient manufacturer as a Drug Master File (DMF)-Type 4 (195). These data are then referenced when an Investigational New Drug application (IND) or New Drug Application (NDA) is filed for a drug dosage form using the excipient.

(From Ref. 198.)

A petition can also be made for approval as a food additive and to be placed on the GRAS (generally regarded as safe) list. The GRAS list (21 Code of Federal Regulations 182.1–184.1) actually applies only to food additives that are reviewed by the FDA and determined to be generally recognized as safe for the purpose and use conditions described in the statute. The use of GRAS excipients is often but not always transferable to oral pharmaceutical formulations. Once the material is approved for use in foods, the material may be considered suitable for use in an oral formulation if the dose fits within the quantities consumed as a food additive. This suitability does not, however, transfer to non-oral routes.

The process is similar in Japan, in that a new excipient's dossier is evaluated in reference to an application for a drug dosage form containing the excipient. The data is evaluated both in terms of the excipient and the active, but only the drug product is approved. After the excipient has seen extensive utilization in multiple marketed products, the regulatory system has a process for review of the data

resulting in possible inclusion of the monograph in the *Japanese Pharmacopoeia* (JP). The JP defines the mandatory standards for substances used in a pharmaceutical product. Inclusion in the JP establishes “precedent” status for the excipient and this notation permits use of the material in new drug products under defined conditions without the need to submit extensive supporting data.

In Japan however, new is new. Even with precedent status, if a new higher dose or a new route of administration is pursued, the examination will treat the excipient as new. This also applies to an approved food additive or cosmetic ingredient. The first use in a pharmaceutical formulation is considered a new use and the application will be examined as such.

Current Regulatory Status of CDs

The parent CDs in Japan are classified as natural starches that have received approval by the Ministries of Health for use in foods. Relative to pharmaceutical applications,

monographs for α - and β -CD have been included in the Japanese Pharmaceutical Excipients (196) compendium (JPE). Even though nine pharmaceutical products with CD formulations have been marketed in Japan, the use of CDs has not been extensive enough in approved formulations to receive "precedent status."

In the United States, two drug products are approved containing CDs (one each containing α -CD and (2HP)- β -CD) and at least one additional NDA has been filed (product containing SBE7- β -CD). In addition, Drug Master Files have been submitted for β - and γ -CD and the (2HP)- β -CD and SBE7-7 β -CD derivatives. These DMFs are available for referencing in IND and NDA applications through agreements with the individual manufacturers. A food additive petition is also under review for β -CD, and a monograph on β -CD has been included in volume 19 of the NF under the name Betadex (197). The United States Pharmacopeial Convention is reviewing proposal(s) to include monographs on additional derivative(s).

An expert panel concluded in 1997 that β -CD is GRAS for its intended use as a flavor carrier and protectant at a level of 2% in numerous food products. The products included chewing gum, graham and puddings, soups prepared from dry mixes, coffee and tea products with added flavors, savory snacks and crackers with added flavorings, baked goods prepared from dry mixes, beverages prepared from dry mixes, and breakfast cereals. A petition has been filed with the FDA requesting their affirmation of β -CD as GRAS for these products. The Joint Expert Committee on Food Additives (JECFA) of the World Health Organization and the Food and Agriculture Organization has reviewed β -CD and established an acceptable daily intake (ADI) of 0–5 mg/kg body weight. The Scientific Committee for Foods of the European Union has also assigned β -CD an ADI of 5 mg/kg body weight/day. The FDA granted GRAS status for γ -CD in 2000.

COMPLEXATION: NON-CYCLODEXTRINS

Galina N. Kalinkova

Medical University, Sofia, Bulgaria

INTRODUCTION

Complexation processes, also known as complexation, are based on the ability of many well-known drugs to interact and to form new complex drugs with altered properties in comparison with a drug alone. The pharmaceutical technology and the pharmaceutical industry have long considered research and development in the area of complexation a priority. The complexation process offers new possibilities for the improvement of existing drugs (side effects, therapeutical activity, and solubility). Such drug complexes with optimized characteristics can be prepared by complexation as a result of various interactions as drug–metal ion, drug–drug, drug–excipient(s), etc.

Today, two of the greatest advances in pharmaceutical technology can be found in the field of complexation processes. These are chelathotherapy and biotechnology. The significance of chelathotherapy is evident in relation to recent increased problems connected with the pollution of the environment.

Biotechnology in relation to the pharmaceutical industry ensures new special drugs, some of which include proteins, antibodies, and peptides. Others include insulin, interferons, growth factors (GFs), and sensitive diagnostics for diseases such as hepatitis, AIDS, and herpes.

It is interesting to note that the history of medical treatment with metal ions and their compounds has been known for thousands of years. In 2500 B.C, the Chinese used gold (Aurum, Au) for medical treatment, whereas in the middle of this past millennium, the gold's compounds were considered an effective treatment against leprosy.

COORDINATION THEORY AND SOME RECENT THEORETICAL CONSIDERATIONS

The coordination theory was promoted by the Swiss chemist Alfred Werner (1866–1919) in 1891. He became a professor in Zurich in 1893, and in 1913, he received the Nobel Prize in Chemistry for his investigations of complex compounds (1). Werner found many nonorganic

compounds with asymmetrical molecules that were also optically active in solutions. Such complex compounds include Co, Cr, and Fe.

The development of the chemistry of complex compounds was also promoted by the Scandinavian scientists K. Blomstrand and S. Jorgensen (1837–1914).

Gilbert Newton Lewis (1875–1946), University of California, contributed to the development of the electronic theory of the valence. He also carried out investigations on absorption spectra of organic compounds.

The atom of the complex-constitutor is the so-called central atom or central ion. In order to emphasize the difference between the central ion of the same metal in a free state, the central ion is marked with the symbol of the chemical element followed by its valency in roman numerals in brackets. Molecules and ions directly bound with the central atom are called coordinated groups (Cl, NH₃, H₂O, etc.) or intraspherical substituents (ligands or addenda) (2–4).

Ligands are “hard” or “soft” (5). The former are electronegative with electrostatic interactions, low delocalization of electron density, and formation of covalent bonds with cations. They include F[−] ions and H₂O molecules. “Soft” ligands are polarizable, covalent bonds, such as chloride, bromide, iodide, sulfur-containing ligands, imidazole, etc. This division into “hard” and “soft” ligands is conventional. It is more correct to consider the series of ligands in their increasing hardness:

It should be noted that complexing ions are characterized with definite steric structures. The most widespread drug complexes with coordination number 6 are built according to the type of the octahedron, with the

Table 1 Drug configurations

Metal ion	Coordination number	Polyhedron type	Schematic presentation
Cu(I)	4	tetrahedron	
	(2)	(chain)	
	(3)	(triangle)	
Cu(II)	4	square	
	6	distorted octahedron	
	(4)	(distorted tetrahedron)	
	(5)	(square-pyramid or trigonal-bipyramid)	 
Ni(II)	4	square	
	4	tetrahedron	
	6	octahedron	
	(5)	(trigonal-bipyramid)	
Co(II)	4	tetrahedron	
	(4)	(square)	
	(5)	(trigonal-bipyramid)	
Co(III)	6	octahedron	
	(4)	(tetrahedron)	
	(5)	(square-pyramid)	
Fe(II)	6	octahedron	
	(4)	(tetrahedron)	
Fe(III)	6	octahedron	
	(4)	(tetrahedron)	
Mn(II)	6	octahedron	
	(4)	(tetrahedron)	
	(4)	(square)	

The parentheses used in the second column mark the addition of nonordinary states.

Fig. 1 Steric structures of *cis*- and *trans*-isomers.

coordinated groups oriented to the octahedron's peaks (Table 1). The drug complexes with coordination number 4 also can be built on the type of tetrahedron or on the type of plane (Table 1).

The steric structures presented explain the early detection of isomery (isomerism) of the complex compounds of Co, Pt, etc., as well as predict the number of geometric(al) isomers of the complex ion. For example, complex ions Mea2b2 may exist as two geometric isomers (*cis*- and *trans*-). The content's complication of the complex ions increases the number of geometric isomers (Fig. 1).

Consideration of the octahedral model in accordance with symmetry knowledge also has been used to predict the presence of the mirror isomerism in complex compounds with definite content and structure. Its discovery was made by Werner in 1911, and is a confirmation of the coordination theory (2, 3).

The first steric ideas were based on the pure chemical ways. The number of the isomers in the substitution reactions was determined by their comparison. These models were confirmed by X-ray diffraction analysis.

COMPLEXES FORMED BY INTERACTIONS WITH METAL IONS

Azathioprine, an immunosuppressant and cytostatic drug, forms complexes with various metal ions (6). The complexes have been investigated by the potentiometric titration method, infrared (IR) spectroscopy, etc. Azathioprine is found to form 2:1 complexes with Co(II), Cu(II), and Ni(II). The order of their stability is established as Cu(II) > Ni(II) > Co(II). Azathioprine-metal complexes have been proven by their IR spectra. The evidence of the effect of complexation was established by the absence of an absorption band at 3191 cm^{-1} (N-H stretching characteristic of a purine function in Azathioprine); e.g., the aminogroup is involved in the formation of the metal complex. The anticancer action of purine derivatives was discovered in 1949. This cytostatic drug biotransforms to 6-mercaptopurine in the body (6).

Fig. 2 The complex formation between Cu(II) ions and carboxylic groups in penicillins.

Drug interactions often constitute major problems in drug therapy. This occurs when metallic therapeutic agents and drugs (able to form complexes) are administered simultaneously (7). The metallic compounds used in pharmaceutical preparations and included in pharmacopoeias are as follows: magnesium trisilicate, aluminum hydroxide, ferrous sulfate, calcium carbonate, sodium bicarbonate, and potassium citrate. Norfloxacin, a 4-Quinolone carboxylic acid derivative with antimicrobial activity, has shown significant interaction with compounds containing Fe^{2+} , Mg^{2+} , and Al^{3+} which have led to less active complexes (unabsorbable and/or antibacterially inactive). Such complex formation is proposed as a factor responsible for the alteration of drug activity by simultaneous co-administration with metallic medicinal agents (7).

Platinum(II) complexes have antitumor activity, and have been tested against P-388 leukemia (derivatives of the substituted *o*-phenylenediamine). Their antitumor activity has been connected with many factors. These include the formation of chelate rings and their strength, the nature and the influence of different substituting groups, and the relative stability of the Pt(II) complexes (8).

Copper(II) complexes of penicillins (benzylpenicillin, phenoxymethylenepenicillin, ampicillin, amoxicillin, and carbanicillin) have been prepared. They have shown stoichiometries of the type CuL^* , CuL_2^* , and CuL_3^* (where L^* penicilloic acids). Structures of coordination penicillin compounds have been suggested by IR spectroscopy as monoatomic bidentate ligands coordinating the Cu(II) ion through the carboxylic groups (Fig. 2).

Copper(II) ions have promoted the hydrolysis of penicillins to corresponding penicilloic acids owing to β -lactam group. The same process has been confirmed between Cu(II) ions and carboxylic groups of cephalosporins, which also belongs to β -lactam antibiotics (9).

Advances include radioprotective drugs applied during radiotherapy of neoplastic diseases (10). Effects similar to

the enzyme superoxide dismutase have been found in copper complexes of Schiff's bases (derived from different amino acids and salicylaldehyde). Activity of complexes is dependent on their structures. The structural changes of their chelate rings are responsible for their effects on free radicals produced in organisms during radiation. Complexes have square pyramidal pentacoordination, which is similar to the coordination polyhedron in the active center of the Cu-dependent superoxide dismutase. The complexes used as radioprotective drugs play an important role in radiotherapy. They protect healthy tissues and cells from injurious radiation (10).

The first natural product in which the presence of the metal cobalt (Co) was shown is Vitamin B₁₂ (cobalaminum). It was isolated from the liver simultaneously by K. Fokers (United States) and Lester Smith (England). The Vitamin B₁₂ structure was established by Todd in 1955. The center of the molecule contains the metal Co(III) with a coordination number 6. It is connected with four mutually bound pyrrol cycles. Vitamin B₁₂ is used in the treatment of pernicious anemia.

COMPLEXES FORMED BY INTERACTIONS WITH EXCIPIENTS

Naltrexone (11) is a potent narcotic antagonist approximately 30–40 times more active than nalorphine, and 2–3 times more active than naloxone. Polymeric complexes as a result of hydrogen bond interactions between Naltrexone and Eudragit[®] have been studied. High performance liquid chromatography (HPLC), ultraviolet (UV) spectrophotometry, scanning electron microscopy (SEM), ¹H- and ¹³C-nuclear magnetic resonance (NMR), differential scanning calorimetry (DSC), and hot stage microscopy (HSM) have been used to characterize naltrexone polymeric complexes. A very high efficiency in the dissolution process, as well as a significant reduction in the drug release rate from the complex, has been observed (11).

Eudragit[®] L (12) is a polymer with anionic character that is based on the methacrylic acid and its methyl ester (in ratio 1:1 approximately; m.w = 135000). Eudragit[®] L is widely used in drug preparations. A proposed complexation process allows the obtainment of Eudragit[®] L-Cardiol complexes. The nature of the latter was established through the use of spectroscopic techniques (IR, ¹H, and ¹³C-NMR). The complex was characterized as intermolecular association (polymer–drug), and the drug interacted with ammonium (maximum cardiolol salt content in complex—22%). Comparative studies of cardiolol and

morphine complexes have shown differences. These differences are explained by the different chemical structures related to the amino group of the two drugs (12).

The excipients ethylcellulose (13) and pectin (14) show the possibilities for complex interactions of the type intermolecular H-bonds. The latter result in increased therapeutic activity of the amoxicillin trihydrate (granules) and nystatin (plaque). The nature and complex character of these interactions have been investigated by means of IR spectroscopy and X-ray diffraction (13, 14).

Indomethacin was introduced into medical practice in 1963. Its anti-inflammatory activity is much greater than aminophenazon and hydrocortisone, and it is a much stronger antipyretic than aminophenazon. The properties of indomethacin in complex formations have been studied. The drug interacts with various agents, such as zinc (15), calcium glycerophosphate (CGP) (16), polycarbophil (17), chitosans (18), 2-(*N,N*-dimethylamino) propionate (19), and eprizole (20). The indomethacin complexes show better characteristics when compared to the drug alone. Improvements in water solubility, increased dissolution and absorption rates, and increased bioavailability have been proven, as well as decreased side effects (gastrointestinal ulceration and hemorrhage). Some of the zinc–indomethacin complex characteristics are as follows: m.p.—232°C (decomposition), IR spectrum—1586 cm⁻¹ (asymmetrical stretching of carboxylate anion), ligand and metal ratio 2:1, and two molecules of crystal water (15).

The preparation methods of Indomethacin complexes and their advantages have been described in detail. These include: 1) Zn–indomethacin (15)—economical and less time consuming; 2) indomethacin–CGP—simplicity, facility of design, and nearly cost-free production (of the complex) on a large scale (industrially (16); 3) the concentration of polycarbophil can be used as a key step in suppositories (17); and 4) indomethacin–epirizole complex (20)—new spherical crystallization technique applied without further processing as granulation.

Propranolol–methacrylic acid copolymer complex (21) has been evaluated as a potential prolonged releasing drug. Propranolol content is found to be 68% in the complex. The complexation process has been defined as positive interaction of a high degree between propranolol and the polymer (specific ion–ion interactions and hydrophobic binding to the overall complexation process). The slow release of propranolol from the complex may be due to hydrogel formation when the drug (the tablet) is exposed to the dissolution medium. The complex has been investigated by differential thermal analysis (DTA) and IR- and UV-spectroscopic methods.

Chitosan is a cationic polymer used for controlled drug delivery. It forms polyion complexes (interpolymer) as a result of its interactions with anionic polymers. The polyion complexes and their basic properties have been investigated for their pharmaceutical application (22). The specific properties of the complexes (chitosan–sodium alginate and chitosan–sodium acrylate) are due mainly to rigidity or flexibility of the polymer chains. The former is stable to pH change, and the latter is quite sensitive to pH change, which makes them applicable to the design of more precisely controlled drug delivery systems. Fourier transform infrared spectroscopy (FTIR), elementary analysis, and viscosity measurements have been used to explain the nature of these complexes (22).

Recently, the tranquilizer action of phenothiazine derivatives has been connected with the flexibility of their molecules (23). They form complexes with charge transition. These complexes have been obtained as a result of the interactions between phenothiazine derivatives, dextrans, and pectins. IR spectroscopy, X-ray diffraction, UV spectroscopy, and Dreiding models (a 3-D research model) have been applied (24). Hypochromic effects (changes in the band's intensity) in UV spectra have been observed. The degree of complex binding correlates with the concentrations of dextrans.

COMPLEXES FORMED BY DRUG–DRUG INTERACTIONS

A new complex of Ind and epirozone (molecular ratio equal to 2:1) has been prepared by the spherical crystallization technique and proven by means of IR spectroscopy and X-ray diffraction (20).

ANALYSIS

Drug complexes require application of numerous methods of analysis (physico-chemical, biological, etc.) for their complete characterization (25). The choice and combination of these methods are connected mainly with their effectiveness in establishing the type of the complexes as well as proving their mechanism. Today, the commercial availability and economical convenience (26, 27) of the drug complexes (their preparation, analysis, and manufacturing) propose a new strategy and balance for pharmaceutical technology (the pharmaceutical industry, respectively). In this context, the combination of IR spectroscopy and X-ray diffraction are methods of choice (28).

Complexes obtained by interactions between aliphatic amines and carboxylic acids (23) have a structure type of the ion pair and complex composition 1:1. Their IR spectra do not have the characteristic absorption band for free $\nu\text{C=O}$ in the region from 1780 to 1700 cm^{-1} . However, new characteristic absorption bands appear for the carboxylate anion in 1680–1560 cm^{-1} ($\nu_{\text{as}} \text{COO}^-$) and 1400–1300 cm^{-1} ($\nu_{\text{s}} \text{COO}^-$). Some additive bands also appear: The vibration NH^+HO^- (in the region 2800–2200 cm^{-1}), as in the salts in solid state, and the bands δNH_2^+ or δNH_3^+ at 1620–1600 cm^{-1} , and δCO_2 at 670 cm^{-1} (where ν is stretching or valence vibration and δ is deformation vibration). The complex with composition 2:1 can be formed as a result from the addition of a second acid molecule to an ion pair (in increased amine concentration). Characteristic absorption band of the carboxylate anion shifts to the lower values of the wave numbers (as compared to the complex with 1:1 composition) (23).

Electron Paramagnetic Resonance

Electron paramagnetic resonance (EPR) gives basic information on the complexes containing Cu and Fe ions (in drugs or proteins) mainly for the character of their bonds and ligands. Free organic radicals also give EPR signals, which makes interpretation of spectra very complicated (29).

Electron Spectra (UV–Visible Spectra)

Usually, the intensive bands appear in UV–visible regions that are connected with the charge transition (between ligand and metal ion or between ligand atoms). The band positions (in charge transition) are dependent on the nature of metal and ligand as well as on their relative ability to oxidation and restoration) (23).

Nuclear Magnetic Resonance (NMR)¹H

These spectra are applicable in conformation analysis, e.g., stereochemistry. They are used to provide very necessary information on the role of metal and on the nature of metal complexes.

Complexometry

This is a quantitative (titrimetric) analysis for drugs containing bismuth (Bi), calcium (Ca), magnesium (Mg), plumbum (Pb), and zinc (Zn), among others. The titration is performed with solutions of polyaminocarboxylic acids and their salts, the so-called complexons (I, II, and III or Trilon B, respectively). They are able to form stable,

water-soluble complexes in stoichiometry (1:1) with the drug metals. The titration is carried out in the presence of one of the metal-indicators used (eriochrome black T, murexide, or xylenolorange). The requirements for the metal indicators include their reversible interactions with the metals of drugs analyzed, unstable complex formation, and color differences in free or complex states (2). Therefore, complexometry is an analysis in principle based on the complex formation ability of some drugs.

CHELATOTHERAPY: COMPLEXATION PROCESSES IN THE HUMAN ORGANISM

The treatment of poisoning with metals includes the use of drug chelating agents. The latter form stable and nontoxic complexes with metals and are quickly eliminated from the body.

Criteria of the Drug Choice as Chelating Agents

Chelathotherapy requires comparative evaluation of the chelating drugs. The following must be taken into consideration when choosing chelating drug agents for a given metal: 1) stable binding with the metal so that it may be concurrent to the biological ligands in the organism; 2) selectivity; and 3) nontoxicity.

The selectivity of the drug ligand to a definite metal can be evaluated by analysis of the formation constant. In cases where the selectivity is decreased or absent, unwanted side effects have been observed as a result of the complexation with other metals (such as calcium and zinc). The chelating drug agents attack heavy metals. In the organism, the metal will be in a lipophilic medium. When the ligand is lipophilic, the lipophilic complex cannot have toxic action. If the ligand is adequately lipophilic, it can penetrate the membrane of the depo metal forming a lipophilic complex (29).

A discussion of some chelating drugs follows.

Dimercaprol (BAL): This drug preparation appeared during the World War I and was used for treatment of battle poisoning along with luisit ($\text{ClHC}=\text{CHAsCl}_2$). The luisit action is based on the binding with $-\text{SH}$ groups.

BAL as a drug ligand makes stable bonds with arsen (As) and, thus, is able to remove it from the luisit molecules. BAL also has been used in the treatment of poisoning with other metals (Hg, Ca, Au, Ti, Tl, and Bi). BAL forms solid (strong) bonds with a series of metals; consequently, it must be used in low concentrations. The use of BAL requires more attention since the organic

compounds of Hg increase their concentrations in the brain in the early stages of the poisoning (30).

EDTA (30): In this drug preparation, calcium is bound as complex and can be displaced from the ions of heavy metals. These metals are bound loosely in the biochemical systems of the tissues and are liberated easily from them.

Water-soluble stable complexes with low toxicity are formed with EDTA and are very rapidly eliminated with urea. EDTA is given by injection in acute and chronic poisoning with Pb, Cd, Co, Hg, U, It, and Ce.

Penicillamine: Penicillamine is used in the treatment of cronic copper accumulation (Wilson's disease).

X-ray diffraction investigations explain the structure of this complex. The central ion is a halogen surrounded with eight Cu(I) atoms with sulfur donors. The coordination sphere of the Cu(II) is completed with amino groups of the penicillamine (29).

Anticancer drugs: Anticancer drugs and their metal complexes appear as *cis*- and *trans*-isomers. The *cis*-isomers of the dichlordiaminoplatin(II) (*cis*-DDP) and the tetrachlordiaminoplatin(IV) are known as the most effective complexes. The former *cis*-isomer of platinum(Pt;II) has a large application in the treatment of cancer of the ovaries and testicles. *Trans*-complexes have shown toxicity and do not possess non-anticancer action.

All of the anticancer drugs (*cis*-DDP) have side effects, such as nausea, diarrhea, decrease of the hemoglobin levels, and destruction of the kidneys. The latter is connected with the difficulty of creating and supporting the high liquid content in patient organisms during treatment.

Thus, it is extremely important to determine the most effective methods that allow in vivo low drug concentrations. Some basic protocols have been established on restoration of in vivo complex Pt(IV), disintegration polymeric platinum compounds, and slow evacuation of blocking inert ligands. Other platinum complexes also have been examined (29).

The method of circular dichroism has been applied in investigations that have determined the reactions between Pt(II) compound and nucleosides, nucleotides, and DNA. Many antimicrobial preparations are excellent ligands. The activity of some of the antimicrobial preparations has been based on their complexing with metal ions. For example, increased effectiveness of tetracycline has been observed after its coordination with Ca^{2+} . The complex is more lipophilic and very oil-soluble, which explains its transportation through the cell membrane. The opposite situation occurs when the ion-metal is toxic and the coordinated antibiotic serves as carrier through the membrane.

Diuretic drug preparations have promoted urine formation. They are derivatives of mercury propanol $\text{RCH}_2\text{CH}(\text{OH})\text{CH}_2\text{HgX}$, where R is a polar hydrophilic group. The mercury diuretic preparations act as ferment inhibitors (latter containing—). They also inhibit adenosine triphosphate (ATP). These properties led to the use of mercury drug compounds in the treatment of bacterial infections. In these cases, they interacted with —SH groups of the bacteria proteins.

Interactions between Drug Preparations and Metal Ions in Humans

Many drug preparations can interact with metal ions. Therefore, they function in humans as chelating agents and form complexes. In some cases the therapeutic activity of a drug compound can be explained by inhibition through a chelated metal ion. For example, disulfiram (tetraethylthiourea disulfide) is used in the treatment of chronic alcoholism. It inhibits aldehyde oxidase, and the ethanol metabolism is interrupted in the stage of formation of the acetaldehyde. The latter leads to an unpleasant feeling. It makes the alcohol (ethanol) nontransportable in its later use. The complex with metal ion can lead to formation of the neutral oil-soluble particles able to penetrate the cell membranes. The metal ion acts as a carrier of the drug substance preparation (29).

Drug preparations able to interact with metal ions include acetazolamide, amphetamine, aspirin, ethambutol, phenacetin, nialamide, disulfiram, and thioacetazone. The evaluation of new drugs includes the emphasis of the following important requirements: 1) the drug's strength and the ways (or mechanisms) of its action; 2) the side effects of the drug and its metabolites; 3) its stability in vivo; and 4) its possible interactions with other drugs.

Consideration of these requirements is extremely important. The possible interactions between two or more drugs, taken simultaneously, make their use dangerous or change their therapeutic activity (either increase or decrease). Only the nonionized drug compounds are oil-soluble. Sometimes, drug preparations do not appear active since some of their metabolites are in pharmacologic active forms. Drug characteristics are connected with the whole drug molecule or with receptors. The degree of ionization of the drug in vivo has been determined by the values of pK_a and pH of the organism liquids. The effectiveness of the sulfonamides against infections is stimulated by the presence of the NH₂ groups. The latter prevents the growth and the multiplication of bacteria. The applications of the metal complexes against numerous microorganisms and against strains highly resistant to the traditional antibiotics have

great importance (29). The form and the distribution of the charges in the complex give information concerning the necessary pharmacological properties.

Metals as Drugs

Lithium (Li) has been used in the treatment of bipolar disorder (manic depression) for approximately 50 years. Over 2000 British patients use Li for this disease. The illness is characterized by alternative states of depression and mania, or overexcitement. At times, the cycle of mood changes continue for several weeks or for one year with good results (intervals) between the phases. In Texas, a correlation has been noted between the influence of Li-salts and the drinking water as well as the increase in visits to psychiatric (mental) public health hospitals.

The compounds of gold were first applied in the treatment of rheumatoid arthritis in 1927, and are used even today in the treatment of severe cases.

Thiomalate (salt of ester of the malic acid) also has been used very successfully to treat severe cases of rheumatoid arthritis. A complete cure or a significant improvement has been noted in approximately 50% of patients using this treatment modality, with 40% of patients exhibiting side effects. Thiomalate is also toxic and possesses cumulative action. Minimal concentrations of the gold compounds reach many cells and remain in the body for years (29).

Complexing and Nonmetals as Microelements

Many nonmetals are important microelements necessary for the normal function of organisms. Some polyvitamin preparations contain microelements as microadding. Their therapeutic and toxic action depends on the concentration. Therefore, the presence of these microelements in the organism in proper amounts is extremely important. Examples of nonmetals include boron (B), silicon (Si), selenium (Se), arsenic (As), chlorine (Cl), fluorine (F), and iodine (I).

Studies on the influence of boron have shown that its compounds as borate have inhibited some fermentative reactions. In addition, the influence of boron results in membrane destruction (29).

The lack of silicon (Si) leads to destruction of bone structure and connective tissues (29).

Deficiency of selenium (Se) influences the concentration of vitamin E. The latter is an antioxidant and protects membranes from oxidation. The ability of Se to protect organisms from the poisoning with Hg or Cd are well known. The normal concentration of this microelement is 0.09–0.2 mg/cm³ (29). Interestingly, the

concentration of Se in the blood of New Zealanders shows a decrease (0.068 mkg/cm^3).

Fluorine (F) and its metabolites are of importance in protecting teeth from caries. Fluorine is included in calcium hydroxyapatite, and it promotes the precipitation of calcium phosphate $\text{Ca}(\text{PO}_3)_2$ and accelerates the remineralization. The necessary concentration of Fluorine added to drinking water to prevent caries is approximately 1 mg/L . Application of higher Fluorine concentrations (above 8 mg/L) leads to fluorosis. This is a disease that is characterized by a disturbance in the function of the thyroid gland. A long-term application of fluorine leads to intensive mineralization (possible precipitation of calcium sulfate), deformation of bones with possible accretion, and calcification of the connections (29).

Iodine (I) has a great role in the function of the thyroid gland. It takes part in a complex biochemical synthesis schema and interacts with hormones. Deficiency of iodine is characterized weakness, feelings of cold and dryness, and yellow-colored skin. The treatment of these symptoms is achieved with iodine or thyroid hormones (29).

BIOTECHNOLOGY

Drugs as special products of biotechnology have an important role in the pharmaceutical industry. Biotechnology is based on the progress of genetic engineering and fermentation technologies. These advances make possible a host of new products, some of which include peptides, proteins, and antibodies, and are used as therapeutics or diagnostics.

Potential drugs, such as interferons, interleukins (as well as other lymphokines), growth factors, and plasminogen activators are also being used as diagnostics. They are very sensitive to many diseases, such as hepatitis, herpes, and AIDS (31).

The beginning of biotechnology stems from 300 small biotechnology companies (often with roots from academic laboratories) that operated in the late 1970s. Today, the list of large American biotechnology companies is long. In addition, the governments of the United Kingdom, France, Germany, and Japan have launched major efforts to assist their countries' development of biotechnology. Some of the large European biotechnology companies include Novo Industri in Denmark and Celltech in the United Kingdom, but the majority of biotechnology companies are in the United States (approximately 75%).

The properties of insulin (5) have been investigated in many ways—as a drug, a protein, and a hormone. Its complex chemical structure has been proven (two

polypeptide chains bound by means of two disulfide bridges). Insulin appears as monomers, dimers, tetramers, or hexamers, depending on the number of its associated molecules. Thus, insulin monomers form dimers, which aggregate in hexamers in the presence of zinc (Zn) in neutral pH. Insulin in concentrations 10^{-5} M (molar) exists as dimers. Many of the latter have been formed as a result of van Der Waal's interactions. Insulin molecules are also bound with hydrophobic forces and hydrogen bonds. The complex chemical structure of insulin explains its ability to take part in complexation processes. Heavy atomic reagents, together with insulin, form various complexes (e.g., with cations of Lantanides, lead [Pb], thallium [Tl], and uranium [divalent group: UO_2]). The latter possesses a linear geometry ($\text{O}=\text{U}=\text{O}$)²⁺. Insulin complexes have been formed with different mercury (Hg) reactants. T.B. Blundell is well known as the British scientist who deciphered the structure of insulin. (He is also known for his work on the building of proteins.) Crystallography of insulin and its complexes have been studied by means of X-ray diffraction and electron microscopy.

The presence of Calcium (Ca^{2+}) is necessary for blood coagulation and subsequently prevents hemorrhaging from tissue injuries. The mechanism consists of cascade-type process in which stages are connected with the presence of Ca^{2+} . Many of the so-called factors of blood coagulation are well known. Vitamin K is necessary in the biosynthesis of the factors IX, X, and VII and of prothrombin. The 1,25-dioxiform of vitamin D_3 facilitates the process of Ca^{2+} reception from the intestines. Accumulation of Ca^{2+} and its release from humans is a complex system, and also includes vitamin D.

Almost all proteins (ferments; redox-, transport- and spare-proteins; hormones; and antibodies) have been studied by X-ray diffraction analysis (5).

Ferments are catalysts. They change the rapidity of the biochemical reactions without displacing the equilibrium ratio.

Redox-proteins are connected with cell organelle as mitochondria, chloroplasts, membranes with specific functions, and high oxidation–reduction potential.

Transport- and spare-proteins (the hemoglobin with its four subunits) ensures the rapid transport of oxygen to a definite place. They have been studied by X-ray diffraction analysis since 1937.

Hormones regulate intracellular metabolic processes. Insulin intensifies transfer (transport) of the glucose in the cell and decreases its level in the circulating blood. Glucagon increases the sugar level in the blood. The two hormones are synthesized by the pancreas. Antibodies discern foreign bodies in an organism.

Fig. 3 Schematic presentation of the complexation processes—drugs and human organism interactions.

DISCUSSION

The preparation of drug complex compounds and the use of their qualitative properties have enormous importance in the pharmaceutical industry. Complex compounds have also taken part in the processes of the vital activity of humans as inner-complex compounds in hemoglobin, tissues, etc. (Fig. 3). Complex bound metals are important components of the ferments (in particular, the oxidative ferments).

A systematic view on the topic of “complexation” and complexes in the literature shows a great number of important research results. This expanding field covers studies of various systems, including antibody–antigen complexes, proteinase–inhibitor complexes (32), lipid-based delivery vehicles, metal complexes with DNA base pair, and aqua ligand in the coordination sphere of metal (33). The metal–modified structures are dominated by these metal-base interactions. However, the structural role of the water molecules in the complexes is quite apparent, as suggested by crystallographic studies (33).

A possibility for the next generation of therapeutics is connected with the complexation processes of proteins with virus membranes, which destabilizes them (34). This knowledge is of interest for future use in genetic medicines. An area of much promise is complexes of polycations with DNA. They result in major improvements. Cationic liposome-based gene delivery accounts for 9–12% of ongoing gene therapy clinical trials in the United States and Europe (35).

Today, many computer programs assist in the investigation of new drug ligand designs, geometry of interactions, and conformational flexibility of the potential ligands (26).

CONCLUSION

Hughes (29) is quite right when he concludes “It is evident today that the metal ions are controlling (are checking) the various biological processes and that life is based on the organic and inorganic chemistry.” Finally, modern pharmaceutical technology has successfully applied the advanced knowledge of many sciences (chemistry, biochemistry, molecular biology, pharmacology, etc.) to solve the various complex problems of drug manufacturing (the pharmaceutical industry) and of drug development. These scientific approaches, to integrate and use all the best of human thought for human health, confirm the pharmaceutical industry as an important interdisciplinary science today and in the future.

Recent research on drug complexation can be described as a tunnel that is being dug from two opposite ends with the efforts of many scientists. On one side are those who solve the problems with drug complexation, while on the other side are those who solve them with protein complexation. When they meet in the middle of the tunnel, the mechanisms of the interactions between drugs and human organisms will be elucidated.

COMPOUNDING, CONTEMPORARY

Lloyd V. Allen, Jr.

International Journal of Pharmaceutical Compounding, Edmond, Oklahoma, U.S.A.

INTRODUCTION

Pharmacists are unique professionals—they are well trained in the natural, physical, and medical sciences and sensitized to the potential tragedy that may result from a single mistake that can occur in the daily practice of their profession. The demonstrated expertise, demeanor, and manner in which pharmacists have practiced over the years has resulted in a continued rating of pharmacists as the most respected and trusted individuals in our society. Pharmacists have the reputation of being available (in the local community) by interacting with patients, providing needed medications, and working with patients to regain or maintain a certain standard or quality of health, as well as just being there in time of need.

Pharmacy is a complex mixture of different practices and practice sites. No longer is pharmacy simply community pharmacy or hospital pharmacy. Pharmacy is diverse and offers many opportunities for those willing to look around, find their niche, and practice pharmacy to meet the needs of their own community of patients. Pharmaceutical compounding is an area that is rapidly growing and providing needed products and services to patients and healthcare practitioners. Most compounding pharmacists appear to be very interested and excited about their practices. In fact, many pharmacists intimately involved in pharmaceutical care have now realized the importance of providing individualized patient care through the preparation of patient specific products. Compounding is a professional prerogative that pharmacists have performed since the beginning of the profession. Even today, definitions of pharmacy include the "preparation of drugs" (1, 2).

Pharmacy is the art or practice of preparing and preserving drugs, and of compounding and dispensing medicines according to the prescriptions of physicians (3).

Compounding has always been a basic part of pharmacy practice; the drugs, dosage forms, and equipment/techniques used are the variables. Pharmacists possess knowledge and skills that are unique and not duplicated by any other profession. Pharmacy activities

that individualize patient therapy include compounding and clinical functions; either activity in the absence of the other results in placing pharmacy in a disadvantaged position. It is important to utilize a pharmacist's expertise to adjust dosage quantities, frequencies and even dosage forms for enhanced compliance. All pharmacists should understand the options presented by compounding.

Pharmaceutical compounding is increasing dramatically due to the impact of home health care, nonavailable drug products (especially pediatric formulations), orphan drugs, veterinary compounding, and biotechnology-derived drug products. Newly evolving dosage forms and therapeutic approaches suggest that compounding of pharmaceuticals and related products specifically for individual patients will become even more common in pharmacy practice.

A pharmacy compounder may be defined as a pharmacist who actively promotes and provides prescription-compounding services for the express purpose of attracting this type of prescription to his or her practice. One of the responsibilities of a compounder requires that the pharmacist become actively engaged in the clinical assessment of a patient in order to assist the prescriber in determining the customized patient-specific formula to be extemporaneously compounded. In addition, this responsibility requires the pharmacist to interact with prescribers and the patient when the customized formulation and dosage form are determined. Previous studies have identified the use of clinical skills and physician/patient interaction as intrinsic factors that enhance a pharmacist's job satisfaction (4–7). Therefore, a compounder who utilizes clinical skills and interacts with prescribers and patients is usually predisposed to a higher job satisfaction than would be a noncompounder whose responsibilities may not require such activities (8).

Pharmaceutical compounding requires the use of one's training in mathematics, science, and technology more than many other practices of pharmacy. It has been stated:

The sciences are what support pharmacy's expertise in drug distribution and drug use. Recent history leads one to question whether we in the profession, and some in pharmaceutical education, recognize

and appreciate the contribution that the pharmaceutical sciences have made and continue to make to the pharmacy profession and health care. The pharmaceutical sciences are what make us unique. They provide us the special value that we bring to the bedside. No other health professional is capable of bringing to the pharmacotherapeutic decision-making table such concepts as pH, particle size, partition coefficient, protein binding, structure–activity relationships, economics, and epidemiology. The pharmaceutical sciences, combined with pharmacy's infrastructure including pharmaceutical education, are what make the pharmacist an indispensable participant on the health care team (9).

Furthermore, what area of pharmacy practice has the opportunity of using the scientific education and training as much as pharmacists involved in individualizing patient care through extemporaneous compounding? The pharmaceutical sciences, especially chemistry and pharmaceuticals, serve as the foundation for pharmacists' ability to formulate specific dosage forms to meet patients' needs.

DEFINITION OF COMPOUNDING

The National Association of Boards of Pharmacy has defined compounding as the following:

Compounding means the preparation, mixing, assembling, packaging, or labeling of a drug or device (i) as the result of a practitioner's prescription drug order or—initiative based on the pharmacist/patient/prescriber relationship in the course of professional practice, or (ii) for the purpose of, as an incident to research, teaching, or chemical analysis and not for sale or dispensing. Compounding also includes the preparation of drugs and devices in anticipation of prescription drug orders based on routine, regularly observed patterns (10).

Compounding may hold different meanings to different pharmacists. It may mean the preparation of oral liquids, topicals, and suppositories. It may include the conversion of one dose or dosage form into another, the preparation of select dosage forms from bulk chemicals, the preparation of intravenous (IV) admixtures, parenteral nutrition solutions, pediatric dosage forms from adult dosage forms, the preparation of radioactive isotopes, or the preparation of cassettes,

syringes, and other devices with drugs for administration in the home setting.

TYPES OF COMPOUNDING

Ambulatory Care Compounding

If one is able to walk, the person is considered mobile or ambulatory, i.e., the individual is not bedridden. Consequently, most pharmacists are involved in ambulatory care and most ambulatory patients are outpatients. The term actually can also be applied to home care patients and even institutionalized patients that are mobile. Ambulatory patients are generally responsible for obtaining their own medication, storing it, preparing it (if necessary), and taking it (11). It seems almost incongruous that in healthcare today, as we become more aware that patients are "individuals," respond as "individuals," and must be treated as "individuals," some healthcare providers appear to be grouping patients into "categories" for treatment and "categories" for reimbursement from third parties. Furthermore, they determine "categories" for levels of care in managed care organizations and use "categorized" fixed-dose products provided by pharmaceutical manufacturers that are available because the marketing demand is sufficiently high to justify their manufacture and production. Since when does the availability, or lack of availability, of a specific commercially available product dictate the therapy of a patient?

Pharmacists have an opportunity to extend their activities in patient care as the emphasis continues to shift from inpatient care to ambulatory care. Ambulatory care can generally encourage a team approach to health improvement, prevention, health maintenance, risk assessment, early detection, management, curative therapy, and rehabilitation (12). Ambulatory care offers a variety of opportunities for individualizing patient care through pharmaceutical compounding. In fact, it is the area where most compounding pharmacists practice.

The pharmacist's role in ambulatory care patients can include the following: 1) dispensing; 2) compounding; 3) counseling; 4) minimizing medication errors; 5) compliance enhancement; 6) therapeutic drug monitoring; and 7) minimizing expenditures (11–13). Most reimbursement for ambulatory patients comes from the dispensing or compounding process. Little financial consideration is given to counseling, minimizing medication errors, compliance enhancement, therapeutic monitoring and minimizing expenditures; however, these

activities are important and should be done. Due to the unique nature of compounded medications, counseling is an absolute must for these patients. From the previous discussion of the activities of an ambulatory care pharmacist, it should be evident that extemporaneous compounding can be vitally important in ambulatory patient care.

Institutional Pharmacy Compounding

The ever-present responsibility of the health care industry is to provide the best available care for the patient, using the best means to do so, and to provide that care in a conducive environment. This requires cooperation on the part of the institutional administration, the medical staff, and the employees (nurses and pharmacists in particular as regards to medication usage). It also must involve the patient. One of the effective means by which institutions, and therefore institutional pharmacies, can meet these challenges is to consider expanding extemporaneous compounding services within the institutional pharmacy. Pharmaceutical care and pharmaceutical compounding can provide cost savings to the institution while providing needed options to the physician through problem-solving approaches, and stimulating the institutional pharmacist through new challenges that allow the expression of both their skills and their art.

Institutional pharmacists have always been actively involved in compounding, or producing medications for the patient. Daily IV therapy is provided through compounding of medications. Antibiotic piggybacks, total parenteral nutrition (TPN) solutions, IV additives, and many others are daily calculated, compounded, dispensed, and generally administered by the nursing staff. The preparation of pediatric dosage forms also has been an area of extensive activity in some institutions.

Members of the institutional staff are constantly reading journal articles and are generally aware of innovative thought and practice by their peers. When physicians become aware of the skill, availability, and awareness of pharmaceutical compounding and that they can literally have almost any medication they need, in the form and strength needed for a specific situation, they generally request it more often. As the institutional pharmacy staff demonstrates their expertise and problem-solving skills, the medical staff consistently calls upon them (14).

In the consideration of meeting patient-specific needs, the institutional pharmacist must look at various modalities as potential solutions. When traditional institutional processes and procedures are not meeting

patients' needs, extemporaneous compounding should be a consideration. Improving outcomes and getting patients well and out of the institution as quickly as possible should be the end goal. Individualized dosage forms, dosage strengths, and alternative routes of administration can often help attain these goals. Improving outcomes will assist the medical staff by allowing them to spend their time dealing with new problems as the hospital pharmacy meets the challenge of past problems. Nursing and pharmacy will have an enhanced opportunity to interest and use the skills they have developed, and provide opportunities for pharmacy to have more patient involvement and job satisfaction.

Veterinary Compounding

The first symposium on veterinary compounding, which occurred in September 1993, was a significant forum for discussion by experts and was a pivotal point in the history of veterinary compounding (15). The meeting was important since it assembled an impressive group of experts on veterinary compounding, who then set about explaining and defining the roles of the veterinarian and the pharmacist.

The Food and Drug Administration's (FDA's) interest in compounding by veterinarians dates back to the beginning of the 1990s. The avowed purpose of the symposium was to provide a forum for a comprehensive, public debate in response to the American Veterinary Medical Association (AVMA) position on compounding prior to the issuance of the FDA Compliance Policy Guide on veterinary compounding. Numerous speakers presented views on compounding by veterinarians and compounding for veterinarians by pharmacists. Topics such as conflicts of interest, lack of compounding training by veterinarians, the "new drug" issue, and bioequivalency standards were discussed in detail.

There are many reasons why veterinary compounding is necessary. For example, with multiple species ranging from very small to extremely large, it would be impossible to practice effective medicine without compounded products! Do we simply refuse to treat exotic species or very small animals? Do we abandon oncology in veterinary medicine?

Also, a more specific area of need is the lack of an ideal anesthetic drug, which has led veterinarians to devise anesthetic combinations that induce good-quality anesthesia with minimal risk to the patient. Compounding is essential for safe and effective veterinary anesthetic practice. Veterinarians need to administer anesthetic drugs to a wide variety of patients with a wide variety of temperaments, in settings that are less than ideal.

Veterinarians are called upon to anesthetize elephants, gorillas, tigers, ostriches, sharks, horses, cows, and poisonous snakes, among others. Other reasons why veterinary compounding is necessary includes: 1) the necessity for multiple injections in the absence of a compounded product; 2) rapid changes in management and disease problems in veterinary medicine; 3) problems associated with the treatment of large numbers of animals with several drugs within a short period of time; 4) cost-prohibitive factors associated with the very large volume of some large-volume parenterals required for animals; and 5) the need for previously prepared antidotes for use in cases of animal poisoning.

Unique aspects of veterinary compounding, as compared to compounding for human patients, include the potential impact on human health of compounded veterinary products in food animals, and variability in animal response and size.

The 1993 symposium expressed the following ideas: 1) veterinarians have a definite need for drug compounding; 2) drug compounding was reported to be necessary in all areas of veterinary medicine; 3) the necessity of compounding poisoning antidotes (e.g., sodium nitrite, sodium thiosulfate, methylene blue, and calcium EDTA).

Veterinary compounding will continue to exist in the future for the same reason as it does now—to fill therapeutic needs in veterinary medicine, as well as in medicine for human patients. Difficulties and costs associated with the veterinary drug-approval process will make compounding necessary to fill therapeutic needs not being met by the introduction of therapeutic agents. An increasing interdependence between the veterinarian and the pharmacist is developing, which will result in higher standards of veterinary care (15).

Nuclear Pharmacy Compounding

Nuclear pharmacy is a specialty practice of pharmacy defined as a patient-oriented service that embodies the scientific knowledge and professional judgment required to improve and promote health through assurance of the safe and efficacious use of radioactive drugs for diagnosis and therapy (16). Radioactive drugs, commonly referred to as radiopharmaceuticals, are a special class of drugs regulated by the FDA. They are unique in that they contain an unstable nuclide (radioactive nuclide) as a part of the compound designed to localize in an organ or tissue. Since radiopharmaceuticals are radioactive, the Nuclear Regulatory Commission, or a similar state agency, is involved in regulatory matters relevant to radiopharmaceuticals.

Most radioactive nuclides employed in radiopharmaceuticals have a short half-life. This is beneficial to the patient, as the total number of radioactive atoms given to the patient to produce an image will be small when the half-life of the radioactive nuclide is short, as compared to longer half-life radioactive nuclides. Fewer total atoms reduce the radiation dose to the patient and thus, the risk from a nuclear medicine procedure. However, the short half-life of the radioactive nuclide results in a short shelf-life for the radiopharmaceutical. As a result, most radiopharmaceuticals are compounded on a daily basis. The most common radioactive nuclide used in the preparation of radiopharmaceuticals is technetium-99m (Tc-99m). Tc-99m has a half-life of 6 h and emits only gamma radiation with an energy almost ideal for detection.

A nuclear pharmacist is expert at preparing (compounding) radiopharmaceuticals with Tc-99m sodium pertechnetate and reagent kits. The kits are multidose vials that contain the compound to be “labeled” with the radioactive nuclide Tc-99m in order to create the radiopharmaceutical. The contents within the vial are sterile and pyrogen free, as is the Tc-99m sodium pertechnetate. Most radiopharmaceuticals are administered intravenously so a nuclear pharmacist is expert at maintaining aseptic conditions during compounding.

The most common setting for the provision of radiopharmaceuticals by nuclear pharmacists is a commercially centralized nuclear pharmacy. Radiopharmaceuticals are prepared early in the morning (2:00–3:00 A.M.) and unit doses are delivered by automobile to hospitals near the nuclear pharmacy.

Today, there are several hundred commercial centralized nuclear pharmacies that provide a large percentage of radiopharmaceuticals used in nuclear medicine procedures. What started as limited service in large medical centers and universities by a few pharmacists with education beyond the Bachelor of Pharmacy degree has grown to extensive services provided by several hundred first professional degree pharmacists. This is truly a remarkable change in a time period of 20–25 years, and has resulted from dedicated entrepreneurs who work to make a difference in patient care through quality products and pharmaceutical care.

HISTORY OF COMPOUNDING

The heritage of pharmacy, spanning some 5000 years, has centered around the provision of pharmaceutical products for patients. Pharmacists are the only health professional who possess the knowledge and skill required to compound and prepare medications to meet the unique

needs of patients. The responsibility to extemporaneously compound safe, effective prescription products for patients who require special care is fundamental to the profession.

The 19th century did not see an end to the art of compounding, but the art did give way, however grudgingly, to new technology. According to estimates, a “broad knowledge of compounding” was still essential for 80% of the prescriptions dispensed in the 1920s. Although pharmacists increasingly relied on chemicals purchased from the manufacturer to make up prescriptions, much remained to be done *secundum artem* (1).

The pharmaceutical industry began to take over the production of most medications used by the medical profession in the mid-1990s. In many ways, this has provided superior service, new methods, and a vast array of innovative products that could not have been provided on a one-on-one basis. Research and development (R&D) have been the hallmarks of the pharmaceutical manufacturers. However, the very nature of providing millions of doses of a product requires that the dosage forms (capsule, tablet, suppository) and doses (individual strengths of each dose) be limited and results in a very one-sided approach to therapy. It is simply not economical for a pharmaceutical company to produce a product in 50 different conceivable doses or 15 different dosage forms to meet the needs of the entire range of persons receiving therapy. Windows of activity that meet the majority of patient needs are determined, but the very nature of the process will not be able to meet all patient needs.

We also must recognize that some individuals and their health care needs do not fall in the “windows” or “categories” of theoretical dosage strength and forms. Furthermore, large-scale manufacturers cannot tailor-make a medication for a handful of patients and do so cost effectively and meet the ever-changing needs of a given patient or institution. The pharmacist’s compounding skill fills in this gap in order to meet individualized needs. By this assessment, the pharmacist, through understanding the principals of compounding and recognition of one’s skill level in working *secundum artem*, may recommend a therapy that is not provided by the pharmaceutical industry, but one that is individualized for a specific patient’s needs at a specific time.

Pharmaceutical compounding is increasing due to the impact of home health care, nonavailable drug products, orphan drugs, veterinary compounding, and biotechnology-derived drug products. Newly evolving dosage forms and therapeutic approaches suggest that compounding of pharmaceuticals and related products specifically for individual patients will become more common in

pharmacy practice. Compounding pharmacy is unique as it allows one to use much of one’s scientific, math, and technology background to a fuller extent than many other types of practices. Compounding pharmacists develop a special and unique relationship with their patients. They work hand-in-hand with physicians to solve problems not addressed by commercially available dosage forms.

TECHNICAL AND OTHER CONSIDERATIONS FOR COMPOUNDING

Some considerations related to compounding a prescription are as follows:

1. Is the product commercially available in the exact dosage form, strength, and packaging?
2. Is the prescription rational, i.e., ingredients, use, dose, and method of administration?
3. Are the physical, chemical, and therapeutic properties appropriate?
4. Will the compounded preparation satisfy the intent of the prescribing physician for the needs of the patient?
5. Is there an alternative dosage form, route of administration, etc. by which the patient could benefit?
6. Can the ingredient identity, quality, and purity be assured?
7. Does the pharmacist have the required training and expertise to prepare the prescription?
8. Are the proper equipment, supplies, and chemicals/drugs available?
9. Does documentation on the use, preparation, stability, administration, and storage of the preparation exist?
10. Can the pharmacist perform the necessary calculations to prepare the product?
11. Can the pharmacist project a reasonable and rational “beyond-use” date for the prescription?
12. Can the pharmacist do some basic quality control to check the preparation prior to dispensing (capsule weight variation, pH, visual observations)?

GUIDELINES AND REGULATIONS FOR COMPOUNDING

Two documents are of special importance in providing regulations and guidelines for pharmaceutical compounding. These include the *United States Pharmacopeia/National Formulary* (Chapters $\leq 795 \geq$ “Pharmacy

Compounding Practices” and ≤1206≥ “Sterile Drug Products for Home Use” and other portions of the USP/NF) and the National Association of Boards of Pharmacy *Good Compounding Practices Applicable to State Licensed Pharmacies*.

United States Pharmacopeia

The following are summaries of the lengthy chapters ≤1161≥ and ≤1206≥ in the USP/NF.

Chapter ≤795≥ “Pharmacy Compounding Practices” (17) is divided into: 1) Compounding Environment, 2) Stability of Compounded Preparations, 3) Ingredient Selection and Calculations, 4) Checklist for Acceptable Strength, Quality, and Purity, 5) Compounded Dosage Forms, 6) Compounding Process, 7) Compounding Records and Documents, 8) Quality Control, and 9) Patient Counseling. The compounding environment section describes guidelines for the facilities and equipment that should be available, calibrated, maintained, and used in a compounding pharmacy. The stability section has been previously cited in this chapter, in part to provide guidelines for “beyond-use” dates to be placed on compounded preparations. The selection of ingredients has been previously discussed in this chapter and sample calculations are presented. The checklist for the USP/NF hallmarks of standards of acceptable strength, quality, and purity is presented in a series of questions to be answered. Examples of compounded dosage forms are discussed along with some precautionary statements, as appropriate. A step-by-step presentation on the compounding process is outlined to ensure uniformity of activities in preparing each preparation. Documentation is described for the Formulation Record, the Compounding Record, and the Material Safety Data Sheets (MSDS) files that should be maintained. The section ends with various aspects for patient counseling involving the proper use, storage, and evidence of instability of the compounded preparation.

Chapter ≤1206≥ “Sterile Drug Products for Home Use” covers the areas of: 1) Responsibility of the Dispensing Pharmacist, 2) Risk Levels, 3) Validation, 4) Low-Risk Operations, 5) High-Risk Operations, 6) Environmental Quality and Control, Finished Product Release Checks and Tests, 7) Storage and Expiration Dating, 8) Maintaining Product Quality and Control After it Leaves the Pharmacy, 9) Patient or Caregiver Training, and 10) Patient Monitoring and Complaint System. The compounding pharmacist dispensing any home sterile drug product is responsible for ensuring that the product has been prepared, labeled, controlled, stored, dispensed, and distributed properly. Low-risk and high-risk levels of

sterile products compounding are defined with examples of each. Validation of the sterilization and aseptic processing procedures are described as related to personnel, facilities/equipment, and processes. Low-risk and high-risk operations are described, along with the validations required for each. Environmental quality and control procedures for the work area and personnel, along with suggested standard operating procedures (SOPs) and an example of an environmental monitoring program, are described. Tests and procedures for the finished product are described with the guidelines that only those products that are free from defects and meeting all quality specifications will be distributed. Guidelines are discussed for preparation, storage, and beyond-use dating after the preparation leaves the pharmacy. After the preparation leaves the pharmacy, the caregiver or patient should receive training to ensure understanding and compliance with the storage, handling, and administration of the preparations. The various aspects of the training program are outlined in this chapter. Also included are the recommendation for written policies and procedures for monitoring of patients using home-use sterile drug products and the handling and reporting of adverse events. It is evident in this chapter that the responsibility of the compounding pharmacist ranges from the activities involved in the compounding of the product through its proper storage, distribution, use, and disposal.

National Association of Boards of Pharmacy

The following is a summary of the Good Compounding Practices (GCPs) of the National Association of Boards of Pharmacy (NABP).

Subpart A contains general provisions and definitions, and sets forth the minimum current good compounding practices for the preparation of drug products by state-licensed pharmacies for dispensing and/or administration to humans or animals and includes definitions and requirements, as follows:

Based on the existence of a pharmacist patient prescriber relationship and the presentation of a valid prescription, pharmacists may compound, in reasonable quantities, drug products that are commercially available in the marketplace. Pharmacists shall receive, store, or use drug substances for compounding that have been made in a FDA-approved facility and/or drug components that meet official compendial requirements. If neither of these requirements can be met, pharmacists shall use their professional judgment to procure alternatives.

Pharmacists may compound drugs in very limited quantities prior to receiving a valid prescription based on a history of receiving valid prescriptions. Pharmacists shall not offer compounded drug products to other state-licensed persons or commercial entities for subsequent resale, except in the course of professional practice for a prescriber to administer to an individual patient.

Subpart B discusses the organization and personnel and the responsibilities and authority of the compounding pharmacist and other individuals involved in the compounding process.

In Subpart C, drug compounding facilities are discussed further in this section. It also discusses bulk drugs and materials as well as the compounding of sterile products, radiopharmaceuticals, and special precaution products, such as handling penicillins.

Subpart D discusses equipment and states that equipment used in the compounding of drug products shall be of appropriate design, adequate size, and suitably located to facilitate operations for its intended use and for its cleaning and maintenance.

In Subpart E control of components and drug product containers and closures are discussed. Components, drug product containers, and closures used in the compounding of drugs shall be handled and stored in a manner to prevent contamination. Their required characteristics are mentioned as well.

Subpart F, Drug Compounding Controls, explains the written procedures for the compounding of drug products in order to assure that the finished products have the identity, strength, quality, and purity they purport or are represented to possess. It also discusses some of the final quality control procedures that can be done, including, but not limited to, the following (as appropriate): 1) capsule weight variation; 2) adequacy of mixing to assure uniformity and homogeneity; and 3) clarity, completeness, or pH of solutions.

Appropriate written procedures designed to prevent microbiological contamination of compounded drug products purporting to be sterile shall be established and followed. Such procedures shall include validation of any sterilization process.

Subpart G explains labeling control of excess products. In the case where a quantity of a compounded drug product in excess of that to be initially dispensed in accordance with Subpart A is prepared, the excess product shall be labeled or documentation referenced with the complete list of ingredients (components), the preparation date, and the assigned expiration date based upon professional judgment, appropriate testing, or published data.

Subpart H discusses records and reports. Any procedures or other records required to be maintained in compliance with these good compounding practices shall be retained for the same period of time as each State requires for the retention of prescription files.

FACILITIES, EQUIPMENT, AND SUPPLIES

Compounding Facility

A separate area for traditional compounding is recommended, rather than simply cleaning off a small area of the dispensing counter. The compounding pharmacist needs a clean, neat, well-lit, and quiet working area. If aseptic compounding is considered, a "clean room" with a laminar airflow hood should be used, dependent also upon the individual state board of pharmacy requirements. The actual facility to be used will depend on the level of compounding to be done.

Adequate lighting and ventilation shall be provided in all drug-compounding areas. Potable water shall be supplied under continuous positive pressure in a plumbing system free of defects that could contribute contamination to any compounded drug product. Adequate washing facilities, easily accessible to the compounding area(s) of the pharmacy, shall be provided. These facilities shall include, but not be limited to, hot and cold water, soap or detergent, and air-driers or single-use towels.

The area(s) used for the compounding of drugs shall be maintained in a clean and sanitary condition. Trash shall be held and disposed of in a timely and sanitary manner.

Compounding Equipment

Much of the equipment used today in compounding has changed. Today, electronic balances are more often used than torsion balances. Micropipets are commonplace and ultrafreezers are sometimes required in addition to standard refrigerator-freezers. This area is constantly changing and the compounding pharmacist should be aware of the available technology necessary to prepare accurate and effective prescriptions. It is very helpful to become acquainted with the local representative for a laboratory supply company.

The equipment needed will be determined by the type and extent of the services one chooses to provide. Hospitals already utilize laminar flow hoods where aseptic compounding of sterile solutions is performed. These

same hoods can be used to compound other sterile products, such as eye drops. A balance, preferably electronic, is essential. Ointment slabs (pill tiles), along with spatulas of different types and materials, should be purchased. A few mortars and pestles (glass, ceramic, and/or plastic) should be obtained, as well as some glassware. It may not be necessary to buy a roomful of equipment, but one should purchase what is needed to start the service and build it as the service grows and expands to different arenas.

Equipment used in the compounding of drug products shall be of suitable composition so that surfaces that contact components, in-process materials, or drug products shall not be reactive, additive, or absorptive so as to alter the safety, identity, strength, quality, or purity of the drug product beyond that desired.

Equipment and utensils used for compounding shall be cleaned and sanitized immediately prior to use to prevent contamination that would alter the safety, identity, strength, quality, or purity of the drug product beyond that desired. In the case of equipment, utensils, and containers/closures used in the compounding of sterile drug products, cleaning, sterilization, and maintenance procedures as set forth in the NABP Model Rules for Sterile Pharmaceuticals must be followed.

Previously cleaned equipment and utensils used for compounding drugs must be protected from contamination prior to use. Immediately prior to the initiation of compounding operations, they must be inspected by the pharmacist and determined to be suitable for use.

Automatic, mechanical, or electronic equipment, or other types of equipment or related systems that will perform a function satisfactorily, may be used in the compounding of drug products. If such equipment is used, it shall be routinely inspected, calibrated (if necessary), or checked to assure proper performance.

Compounding Supplies

Throughout history, pharmacists have been using chemicals and other materials for prescription compounding. In the past, these chemicals and materials have been obtained from natural products, raw materials, and household ingredients. Today, compounding pharmacists use chemicals from various sources, depending upon their availability.

The <795> “Pharmacy Compounding Practices” monograph in the USP 24/NF 19 states as follows (17):

A USP or NF grade drug substance is the preferred source of ingredients for compounding all drug preparations. If that is not available, the use of another high-quality source, such as analytical reagent (AR) or certified American Chemical Society (ACS) grade, is an option for professional judgment. If the substance is not an official preparation or substance, additional information, such as a certificate of analysis, needs to be obtained by the pharmacist to ensure its suitability.

A manufactured drug product may be a source of an active ingredient. Only manufactured drugs from containers labeled with a batch control number and a future expiration date are acceptable as a potential source of active ingredients. When compounding with manufactured drug products, the pharmacist must consider all ingredients present in the drug product relative to the intended use of the compounded preparation.

In summary, it is the responsibility of the pharmacist to select the “most appropriate” quality of chemical for compounding, beginning with the USP/NF as the first choice and, if this is not available, then descend

Table 1 Description of chemical grades

Grade	Description
Technical or commercial	Indeterminate quality
Chemically pure (CP)	More refined but still of unknown quality
USP/NF	Meets minimum purity standards; conforms to tolerances set by the <i>USP 23/NF 18</i> for contaminants dangerous to health
ACS reagent	High purity; conforms to minimum specifications set by the Reagent Chemicals Committee of the American Chemical Society
AR	Very high purity
HPLC	Solvents purified for use in HPLC; very high purity
Spectroscopic grade	Very high purity
Primary standard	Highest purity; required for accurate volumetric analysis (for standard solutions)

the list of purity grades (Table 1), using professional judgment and discretion. A certificate of analysis for the chemicals should be obtained and kept on file in the pharmacy for these selected chemicals (17, 18).

STABILITY OF COMPOUNDED PREPARATIONS

Stability is the extent to which a product retains, within specified limits and throughout its period of storage and use, the same properties and characteristics that it possessed at the time of its preparation. Chemical stability is important when selecting storage conditions (temperature, light, humidity), selecting the proper container for dispensing (glass versus plastic, clear versus amber or opaque, cap liners), and for anticipating interactions when mixing drugs and dosage forms.

Factors Affecting Stability

An important component of compounding is the consideration of factors that affect the stability of the final preparation. These factors include pH, temperature, solvent, light, air (oxygen, carbon dioxide, moisture), humidity, particle size, ionic strength, dielectric constant, polymorphism, crystallization, vaporization, and adsorption.

Types and Examples of Stability

Five types of stability are defined by the USP/NF, three of which will be described. Physical stability is concerned with the original physical properties of the preparation, and include appearance, palatability, uniformity, dissolution and suspendability. Chemical stability states that each active ingredient retains its chemical integrity and labeled potency within specified limits.

Microbiological stability states that sterility or resistance to microbial growth is retained according to the specified requirements. Antimicrobial agents that are present will retain their effectiveness within specified limits.

Beyond-Use Dating

Whereas commercially manufactured products are required to possess an "expiration date," compounded products are assigned a "beyond-use" date. Numerous sources of information can be utilized in determining an appropriate "beyond-use" date, such as chemical companies, manufacturers literature, laboratory data, journals,

and published books on the subject. Generally, most pharmacists prepare/dispense small quantities of compounded products, recommend storage at room, cool, or cold temperatures, and use a conservative "beyond-use" date.

The guidelines published in the USP 24/NF 19 Chapter <795> entitled "Pharmacy Compounding Practices" state that:

In the absence of stability information that is applicable to a specific drug and preparation, the following maximum beyond-use dates are recommended for nonsterile compounded drug preparations that are packaged in tight, light-resistant containers and stored at controlled room temperature unless otherwise indicated.

For nonaqueous liquids and solid formulations (where the manufactured drug product is the source of active ingredient), the beyond-use date is not later than 25% of the time remaining until the product's expiration date or 6 months, whichever is earlier.

A USP or NF substance is the source of active ingredient-the beyond-use date is not later than 6 months. For water-containing formulations (prepared from ingredients in solid form)-the beyond-use date is not later than 14 days when stored at cold temperatures.

For all other formulations-the beyond-use date is not later than the intended duration of therapy or 30 days, whichever is earlier. These beyond-use date limits may be exceeded when there is supporting valid scientific stability information that is directly applicable to the specific preparation (i.e., the *same* drug concentration range, pH, excipients, vehicle, water content, etc.) (17).

COMPOUNDING QUALITY CONTROL

Physical Tests

Pharmacists can perform a number of physical quality control tests to ensure the uniformity and accuracy of many small-scale compounded preparations. These quality control tests include individual dosage unit weights, average individual dosage unit weights, total product weight, pH, and physical observations such as appearance, taste, and smell.

Physical Observations

Physical observations can include color, clarity, uniform distribution, hardening, brittleness, softening, discoloration, expansion/distortion, caking, odor, precipitation, discoloration, haziness, gas formation, clarity, breaking, creaming, difficulty in resuspending, consistency, grittiness, dryness, shrinkage, water evaporation, shriveling, and the presence of oil stains on packaging.

Sterile Products Testing

If appropriate, due to the number of sterile preparations compounded, products may be tested for sterility and the effectiveness of incorporated preservatives, if present. This may be done either at the pharmacy or in a contract laboratory.

Pyrogen Testing

Pyrogen testing should be done especially if sterile preparations are made from nonsterile bulk materials. This testing can be done either at the pharmacy or in a contract laboratory.

Contract Analytical Laboratories

Contract analytical testing can be utilized for purity, potency, sterility, and pyrogenicity testing. The frequency of testing is generally related to the volume and frequency of product preparation.

FLAVORS, SWEETENERS, AND COLORS

Preparation of an Aesthetic Product

Flavoring, sweetening, and coloring are important to enhance patient compliance when medications are administered orally. Oftentimes, these can be adjusted to meet the preferences of the patient.

Basics and Examples of Flavoring

Pharmacists must be familiar with the four primary tastes (sweet, sour, salty, and bitter) and be aware of the correlations between select chemical properties and taste and odor. Using this information, they can use a number of approaches to prepare an acceptable product to minimize the bad taste of drugs. These approaches include blending,

overshadowing, physical methods (insoluble compounds, emulsification, effervescence, viscosity), chemical methods (adsorption, complexation), and physiological techniques (cooling due to negative heat of solution anesthetic action of some ingredients). Also, flavor intensifiers can be used, including citrus enhancers, such as citric, maleic, or tartaric acids.

Basics and Examples of Sweetening

A number of different types of sweeteners, caloric and noncaloric, are available, depending upon the specific prescription and patient. Some sweeteners have aftertastes that must also be considered. Today, patients also can have their choice of natural or synthetic sweeteners.

Basics and Examples of Coloring

Coloring is not always necessary but may be of value in certain medications. For example, oral liquids are generally colored with a dye that matches the flavor of the medication. Pharmacists must be aware of the different oil, alcohol, and water solubilities of the dyes they use.

PRESERVATION, STERILIZATION, AND DEPYROGENATION

Methods of Preservation

Some compounded preparations are naturally preserved, as in the case of some syrups and elixirs. Others require the addition of a preservative. Preservatives are commonly added to products to minimize microbial growth, as in the case of oral liquids, topicals, and multi-dose parenterals.

Physicochemical Considerations in Preservation

A preservative is selected based upon its characteristics, including concentration, pH, taste, odor, and solubility.

Preservative Effectiveness Testing

In some situations, it is advisable to have a preservative effectiveness test conducted on a preparation that may

require routine compounding or may require an extended storage period.

Methods of Sterilization

Compounding pharmacists routinely use in-process sterilization, such as sterile filtration, or terminal sterilization, such as autoclaving or dry-heat sterilization. In some situations, combinations of these methods may be used along with chemical sterilization.

Methods of Depyrogenation

Depyrogenation methods used by compounding pharmacists include dry heat and rinsing with Sterile Water for Injection, USP.

COMPOUNDING PHARMACEUTICAL SOLIDS

Powders and Granules

Powders are thorough mixtures of dry, finely divided drugs and excipients that are intended for internal or external use. Granules are dosage forms that consist of particles ranging in size from about 4–10 mesh. Both powders and granules are easy to use and are easy to compound. An example formula of a currently compounded powder includes the following:

Rx Misoprostol	600 g
Lidocaine hydrochloride	500 mg
Polyox WSR-301	2.45 g
Methocel E4M Premium	22.05 g

Capsules

Capsules are dosage forms in which unit doses of powder, semisolid, or liquid drugs are enclosed within either a hard or a soft envelope or shell. Examples of currently compounded capsules include the following with the contents either as powders, in oil or in a semisolid-fill capsule, as well as modified strength capsules:

Rx Dextromethorphan Hydrobromide 30 mg and Morphine Sulfate 10 mg Capsules (#100)	
Dextromethorphan hydrobromide	3 g
Morphine sulfate	1 g
Lactose	35.5 g
Capsule size #1	#100

Rx Triple Estrogen 2.5 mg Slow-Release Capsules (#100)	
Estriol	200 mg
Estrone	25 mg
Estradiol	25 mg
Methocel E4M Premium	10 g
Lactose	23.75
Capsule size #1	#100

Rx Triple Estrogen 2.5 mg in Oil Capsules (#100)	
Estriol	200 mg
Estrone	25 mg
Estradiol	25 mg
Peanut oil	20 ml (18.38 g)
Capsules size #1	#100

Rx Triple Estrogen 2.5 mg Semisolid-Filled, Hard-Gelatin Capsules (#100)	
Estriol	200 mg
Estrone	25 mg
Estradiol	25 mg
Polyethylene glycol 1450	20 g
Polyethylene glycol 3350	20 g
Capsules size #1	#100

Tablets

Tablets are solid dosage forms that are generally either compressed or prepared by a sintering process, which includes sublingual, buccal, chewable, effervescent, and compressed tablets. Some of these can be easily compounded. An example of a tablet triturate is as follows:

Rx Sodium Fluoride 2.2 mg Tablet Triturates (#100)	
Sodium fluoride	220 mg
Sucrose, powdered	1.15 g
Lactose, hydrous	4.63 g

Lozenges/Troches

Lozenges/troches are solid preparations designed to dissolve or disintegrate slowly in the mouth. Their base is usually flavored and sweetened. Examples of compounded troches include anesthetic (lidocaine), hormonal (testosterone), analgesic (ketamine), and anti-fungal (nystatin) preparations.

Rx Testosterone 10 mg Troches (#24)	
Testosterone	240 mg
Aspartame	500 mg
Silica gel	480 mg
Acacia	360 mg
Flavor	qs
Polyethylene glycol 1450	23 g

Rx Pediatric Chewable Gummy Gels

Active drug	qs
Bentonite	500 mg
Aspartame	550 mg
Acacia powder	500 mg
Citric acid monohydrate	700 mg
Flavor	qs
Gummy gel base	26.6 g

Rx Gummy Gel Base

Gelatin	43.4 g
Glycerin	155 ml
Purified water	21.6 ml

Rx Nystatin Popsicles (#10)

Nystatin powder	2,500,000 units
Sorbitol 70% solution	20 ml
Simple syrup	50 ml
Flavor	qs
Purified water qs	300 ml

Rx Tetracaine 20 mg Lollipops (#30)

Tetracaine HCl	600 mg
Lemon essence	0.5 ml
Green food color	2 ml
Sucrose	150 g
Potassium bitartrate	500 mg
Purified water	55 ml

Suppositories

Suppositories are solid dosage forms that are used to administer medicine through the rectum, vagina, or urethra. They are of different sizes or shapes, depending upon the body orifice for their administration. Examples of compounded suppositories include the antinauseant combinations (lorazepam, diphenhydramine, haloperidol, and metoclopramide), analgesic (morphine), antifungal, and hemorrhoidal (lidocaine, tannic acid) preparations.

Rx Fluconazole 200 mg Vaginal Suppositories

Fluconazole	200 mg
Polyethylene glycol base	qs

Rx Morphine Sulfate Slow-Release Suppositories (#1)

Morphine sulfate	50 mg
Alginic acid	25%
Witepsol H-15	qs

Sticks

Sticks are a convenient form of administering topical medications and come in different sizes and shapes. They are readily transportable and can be easily compounded.

Rx Gralla Type Antiemetic Suppositories

<i>Ingredient</i>	#1	#2	#3	#4	#5	#6	#7
Metoclopramide HCl	10	—	20	10	40	20	20
Haloperidol	0.5	5	—	—	1	1	—
Diphenhydramine HCl	—	25	25	—	25	25	25
Dexamethasone	—	—	10	—	10	10	5
Lorazepam	0.5	2	—	—	1	—	—
Diazepam	—	—	—	5	—	—	—
Hydroxyzine HCl	25	—	—	—	—	—	—
Promethazine HCl	—	—	—	25	—	—	—
Benzotropine mesylate	—	—	—	—	1	—	—
Silicon dioxide	20	30	20	15	—	—	—
Fatty acid base qs	2g	—	2g	2g	2g	2g	2g
Polyethylene glycol base qs	—	2g	—	—	—	—	—

Examples of compounded sticks include those containing antivirals for herpes and emollients/sunscreens for environmental exposure.

Rx Fluorouracil 5% Topical Stick (25-g tubes)

Fluorouracil	5 g
Polyethylene glycol 3350	27 g
Polyethylene glycol 300	68 g

Rx Acyclovir Stick with Sunscreen (five 5-g tubes)

Acyclovir 200 mg capsules	#5
<i>para</i> -Aminobenzoic acid	150 mg
Silica gel, micronized	120 mg
Polyethylene glycol 3350	6.5 g
Polyethylene glycol 300	15 ml

COMPOUNDING PHARMACEUTICAL LIQUIDS

Solutions

Solutions are liquid preparations that contain one or more drug substances molecularly dispersed in a suitable solvent or a mixture of mutually miscible solvents. Solutions include those for use topically as well as internally.

Rx Dexamethasone and Lidocaine Solution for Iontophoresis (100 ml)

Dexamethasone sodium phosphate	200 mg
Lidocaine hydrochloride	1 g
Sterile water for injection	100 ml

Rx Buprenorphine Hydrochloride 150 mg/100 ml Nasal Spray (100 ml)

Buprenorphine hydrochloride	150 mg
Glycerin	5 ml
Methylparaben	200 mg
0.9% Sodium chloride injection	95 ml

Examples of compounded liquids include topicals (wart solutions), oral syrups and elixirs, nasal solutions, otic solutions, iontophoretic solutions (dexamethasone sodium phosphate), and many others.

Suspensions

Suspensions are two-phase systems that consist of a finely divided solid dispersed in a liquid, solid, or gas. They are appropriate when the drug to be incorporated is not sufficiently soluble in an ordinary solvent or cosolvent system. They are used orally and topically. Examples of compounded suspensions include many pediatric oral liquids where a commercial pediatric dosage form is not available. Commercial tablets and capsules are formulated into a vehicle for the patient and can be individually flavored to the patient's preferences.

Rx Indomethacin 4% Topical Spray (100 ml)

Indomethacin	4 g
Hydroxypropyl cellulose	200 mg
Sodium lauryl sulfate	100 mg
Purified water	10 ml
Alcohol, 95% qs	100 ml

Rx Testosterone 10 mg/0.1 ml Sublingual Drops (10 ml)

Testosterone	1 g
Saccharin	100 mg
Silica gel	200 gm
Flavor	qs
Almond oil qs	10 ml

Emulsions

Emulsions are heterogeneous systems consisting of at least one immiscible liquid that is intimately dispersed in another liquid in the form of droplets or globules, whose diameters generally exceed 0.1 micron. They are also thermodynamically unstable mixtures of two essentially immiscible liquids and an emulsifying agent that helps hold them together. Examples of compounded emulsions include those for both topical and oral used. Topical emulsions include creams and even liposomal

Rx Emulsion Base

Mineral oil, heavy	25 ml
Isopropyl myristate	25 ml
Polysorbate 80	7 ml
Methylparaben	200 mg
Propylparaben	100 mg
Purified water qs	100 ml

preparations. Compounded emulsions include preparations for both oral and topical use. This category also includes the pluronic-lecithin-organogels, which are penetration-enhancing gels.

Rx Ketamine 10% in Pluronic Lecithin Organogel

Ketamine hydrochloride	10 g
Isopropyl palmitate:Soy lecithin 1:1	20 g
Pluronic F127 20% gel qs	100 ml

COMPOUNDING PHARMACEUTICAL SEMISOLIDS

Ointments and Pastes

Ointments are semisolid preparations that are intended to be applied externally to the skin or mucous membranes. They soften or melt at room temperature. Pastes are thick, stiff ointments that ordinarily do not flow at body temperature and thus protect and coat the areas to which they are applied. Examples of compounded ointments and pastes include the following:

Note: The testosterone-menthol eutectic mixture can be prepared by mixing 31.6 g of testosterone with 68.4 g menthol, using sufficient methyl alcohol to dissolve them both and allowing the alcohol to evaporate to dryness.

Rx Testosterone–Menthol Eutectic Ointment (2% Testosterone)

Testosterone–menthol eutectic mixture	6.33 g
Hydrophilic petrolatum	93.67 g

Rx Aluminum Acetate Paste (100 g)

Aluminum acetate solution	17 ml
Anhydrous lanolin	34 g
Lassar's Plain Zinc Paste	49 g

Creams

Creams are opaque, soft solids or thick liquids intended for external application. Creams may contain medications dissolved or suspended in water-soluble or vanishing cream bases and can be either water-in-oil or oil-in-water. Examples of creams are as follows:

Rx Progesterone 5% Cream

Micronized progesterone	5 g
Glycerin	qs
Hydrophilic ointment	95 g

Note: Commercial oil-in-water vehicles can be used and the quantity of progesterone is variable.

Gels

Gels are semisolid systems that consist of suspensions made up of either small inorganic particles or large organic molecules interpenetrated by a liquid. Some gels are clear and others are turbid since their ingredients may or not be completely molecularly dispersed or they may form aggregates, which disperse light. Examples of compounded gels include many topical, oral cavity, and even rectally administered preparations, such as the following:

Rx Piroxicam Topical Gel	
Hydroxypropylcellulose	1.75 g
70% isopropyl alcohol	98.25 ml
Propylene glycol	4.1 ml
Polysorbate 80	1.7 ml
Piroxicam 20-mg capsules	25 capsules
(Piroxicam powder can be used, if available.)	

Rx Ketoprofen, Topical Gel Cyclobenzaprine and Lidocaine	
Ketoprofen	10 g
Cyclobenzaprine hydrochloride	1 g
Lidocaine	5 g
Propylene glycol	10 ml
Sorbic acid	200 mg
Lecithin:isopropyl palmitate solution	20 g

COMPOUNDING STERILE PREPARATIONS

Ophthalmics

Ophthalmic preparations are sterile, free from foreign particles, and prepared especially for instillation into the eye. They include solutions, suspensions, and ointments. Examples of compounded ophthalmics include drugs such as acetylcysteine, acyclovir, alteplase, amikacin, amphotericin B, ascorbic acid, bacitracin, calcium gluconate, penicillins, cephalosporins, aminoglycosides, cromolyn, cyclosporin, deferoxamine, anti-inflammatory corticosteroids, chelating agent, oncology agents, and numerous others prepared as both solutions and ointments.

Rx Acetylcysteine 15% Ophthalmic Solution	
Acetylcysteine	15 g
Sterile water for injection qs	100 ml
Sodium hydroxide to pH of 6 to 7.5	

Inhalation Solutions

Inhalation solutions are designed to deliver a drug into the respiratory tree of a patient for either a local or systemic effect. Examples of compounded inhalation solutions include individual and combinations of albuterol, cromolyn, morphine sulfate, corticosteroids, ipratropium, metaproterenol, terbutaline, and others.

Rx Morphine Sulfate 0.25% Inhalation Solution	
Morphine sulfate	250 mg
Citric acid, hydrous	100 mg
Sterile water for injection, qs	100 ml

Rx Albuterol Sulfate and Ipratropium Bromide Inhalation Solution	
Albuterol sulfate	100 mg
Ipratropium bromide	16.7 mg
Benzalkonium chloride 50% solution	0.003 ml
0.9% Sodium Chloride Injection qs	100 ml

Parenterals

Parenterals are products that are administered to the body by injection. They must be sterile, nonpyrogenic, and particulate-free. Examples of compounded parenterals include high-dose analgesics for patient-controlled analgesia (morphine sulfate 50 mg/ml), antiemetic injections, fentanyl and bupivacaine injections for ambulatory pump reservoirs, oncology combinations, and others.

Rx Reglan, Ativan and Compazine Injection		
Reglan (5 mg/ml)	30 ml	150 mg
Ativan (2 mg/ml)	0.5 ml	1 mg
Mannitol 25%	50 ml	12.5 mg
Compazine (5 mg/ml)	2 ml	10 mg
5% Dextrose injection		50 ml

Rx Fentanyl Citrate 1.25 g/ml, Bupivacaine Hydrochloride 0.4375 mg/ml, Epinephrine Hydrochloride 0.69 g/ml		
Fentanyl citrate 50 µg/ml		2.5 ml
Bupivacaine hydrochloride, 0.5%		8.75 ml
Epinephrine hydrochloride, 1:100,000		6.9 ml
0.9% sodium chloride injection		81.85 ml

Rx TPN Solution	
50% Dextrose injection	500 ml
Amino acids 8.5% with Lytes	500 ml
Lipids 10%	200 ml
Calcium gluconate	1 g
Magnesium sulfate	ss2 g
Trace elements	1 unit
M.V.I.-12	1 unit

COMPOUNDING WITH BIOTECHNOLOGY PREPARATIONS

Definitions

Biotechnology preparations are those that are developed using the techniques of engineering and technology with living organisms. Biotechnology presents compounding pharmacists with a unique and new source of therapeutic agents that may require their special expertise.

Types of Preparations

Biotechnology products differ in their method of preparation and potential problems presented in their formulation. Pharmacists involved in compounding with biologically active proteins will be interested in their stabilization, formulation, and delivery. Most of the biotechnology products currently are proteins but some may soon be smaller peptide-like molecules.

Physicochemical Considerations

In working with biotechnology-derived drugs, the compounding pharmacist must be cognizant of both the active drug constituent and the total drug delivery system or carrier. Proteins are generally very potent and used in very low concentrations. Pharmacists must be aware of the vehicle, buffer, and stabilizer requirements for these preparations, including the use of surfactants, amino acids, polyhydric alcohols, fatty acids, proteins, antioxidants, reducing agents, and metal ions. Proper pH, chelating agents, preservatives and tonicity-adjusting agents must be considered.

Quality Control and Stability

One must be aware of the factors involved in handling proteins in order to retain a drug's biologic activity up to the time when it is administered to the patient. Proteins are inherently unstable molecules and their degradation profiles can be very complex. Compounding pharmacists may be involved in the selection of an appropriate vehicle for drug delivery, individualizing dosages, administering drugs through novel drug delivery systems, preparing drugs for delivery through these systems, monitoring their efficacy, and counseling patients on their use.

An example of a compounded prescription using a biotechnology-derived product is as follows:

Rx Tissue Plasminogen Activator 25 mg/100 L	
Ophthalmic Solution	
Tissue plasminogen activator	20 mg vial
0.9% Sodium chloride injection	60 ml
Sterile water for injection	20 ml

COMPOUNDING VETERINARY PREPARATIONS

Guidelines for Veterinary Compounding

Veterinary compounding can be considered when there are no effective FDA-approved products available, when available dosage forms are inappropriate, when multiple and concurrent disease states are present, when an additive therapeutic effect could be obtained from simultaneous administration of two or more products or to minimize side effects, when economic realities would preclude treatment with the approved product, and when compounding would encourage compliance of dosage/therapeutic regimens.

Considerations in Veterinary Compounding

Most drugs that are FDA-approved are specified for certain species, either food producing or for a large target population. If veterinarian pharmaceutical companies do not perceive a sufficiently large market for a product, they will not seek approval for products. This has left a large vacuum, or a potential market, to be filled by compounding pharmacists. There are no FDA-approved products for exotic species due to the limited market and there are only limited FDA-approved products for some of the more common species. Veterinarians need patient-specific products and pharmacists know how to prepare these products. Consequently, a team approach has developed to the benefit of the veterinarian, pharmacist, and animal patient.

Questions that often arise include the following. What is the overall goal of the treatment of this animal? Are there any commercially available products that can be used? What are the regulatory concerns? Is this a food or a milk-producing animal? Will there be a residue problem? What do we know about the physical and chemical compatibility of these drugs? What do we know about the stability of these drugs before, during, and after the compounding process? What do we know about the pharmacokinetics of the active ingredients? Are personnel going to be at risk from handling the drug during compounding or while using the compounding form?

Examples of some veterinary preparations are as follows:

Rx Acetylcysteine, Gentamicin and Atropine Solution

Acetylcysteine	720 mg
Gentamicin (as gentamicin sulfate)	36 mg
Atropine sulfate	36 mg
Sterile water qs	15 ml

Rx 4-Methyl-pyrazole Solution

4-Methyl-pyrazole	1 g
Polyethylene glycol 400	9 ml
Bacteriostatic water for injection qs	20 ml

SUMMARY

Pharmacy compounding provides pharmacists with a unique opportunity to practice their time-honored profession. It will become an even more important part of pharmacy practice in the future, and include pharmacists involved in community, hospital, nursing home, home health care, veterinary, and specialty practices. Pharmaceutical compounding is a practice where the clinical expertise of pharmacists can be merged with the scientific expertise of pharmacists to make pharmaceutical care a reality.

COPRECIPITATES AND MELTS

Madhu K. Vadnere

NJ Pharma LLC, Chatham, New Jersey, U.S.A.

INTRODUCTION

The bioavailability of a poorly water-soluble drug is often limited by its dissolution rate, which in turn is controlled by the surface area available for dissolution. The effect of the particle size of a drug on its dissolution rate and its biological activity is well known. For example, Atkinson et al. (1) reported that micronization of griseofulvin resulted in reduction of the therapeutic dose by half.

The conventional methods for reducing particle size and increasing surface area include trituration, grinding, ball milling, fluid energy micronization, and controlled precipitation (2). Coprecipitates and melts are solid dispersions that provide a means of reducing particle size to the molecular level. Sekiguchi and Obi (3) first introduced the concept of using solid dispersions to improve bioavailability of poorly water-soluble drugs in 1961. They demonstrated that the eutectic of sulfathiazole and the physiologically inert water-soluble carrier urea exhibited higher absorption and excretion after oral administration than sulfathiazole alone. Recent work on solid dispersions has been extended to the development of sustained-release preparations.

DEFINITIONS AND METHODS OF PREPARATION

Definitions

Chiou and Riegelman (2) defined the term solid dispersion as “a dispersion of one or more active ingredients in an inert carrier or matrix at solid state prepared by the melting (fusion), solvent, or melting-solvent method.” Dispersions obtained through the fusion process are often called melts, and those obtained by the solvent method are frequently referred to as coprecipitates or coevaporates. Examples include sulfathiazole-providone (PVP; 4) and reserpine PVP (5).

Methods of Preparation

The two basic procedures used to prepare solid dispersions are the fusion and cosolvent techniques. Modifications of

these methods and combinations of them have also been used (2). Recently, application of supercritical fluid process has been explored to form pharmaceutical solid dispersions (6).

Melting or Fusion Method

This method was first reported by Sekiguchi and Obi (3). A physical mixture of an active agent and a water-soluble carrier is heated until it is melted. The melt is solidified rapidly in an ice bath under vigorous stirring, pulverizing and then sieving. Rapid congealing is desirable because it results in supersaturation of the drug as a result of entrapment of solute molecules in the solvent matrix by instantaneous solidification. The solidification process can be achieved on stainless steel plates attached to a cooling system to favor rapid heat loss. Spray congealing from a modified spray drier onto a cold metal surface has also been used. Products from this process can be obtained in pellet form without the necessity of a grinding step that may alter crystalline modification.

Two advantages of the melt method are its simplicity and its economy, as no solvents are involved. However, the method may not be suitable if the drug or the carrier is unstable at the fusion temperature or evaporates at high temperatures. Succinic acid, for example, used as a carrier for griseofulvin, is quite volatile and partially decomposes by dehydration near its melting point. Such problems can be avoided by melting in a sealed container under vacuum or under an inert gas, such as nitrogen. By proper selection of carrier system and composition, the melting point of a binary system can be much lower than the melting point of either of the components.

Other disadvantages of this method may include the tacky and intractable nature of the resulting solidified melt and irregular crystallization owing to the presence of a miscibility gap on the phase diagram for a given drug-carrier system.

Solvent Method

Tachibana and Nakamura (7) first used this method to prepare a solid dispersion of β -carotene in PVP by using

chloroform as a cosolvent. The solvent is usually removed by evaporation under reduced pressure at varying temperatures. The choice of solvent and its removal rate are critical to the quality of the dispersion. A mixed solvent system may be used. Some examples of solid dispersions prepared by this method include sulfathiazole-PVP (4), reserpine-PVP (5), reserpine-deoxycholic acid (8) and griseofulvin-PVP (9).

The freeze-drying process has been used to prepare dispersions of ketoprofen (10) and dicumarol (11) in PVP from their ammoniacal solutions. Similarly, the spray-drying process has been used to prepare dispersions of acetohexamide in PVP (12) and chlorthalidone in pentaerythritol (13).

The major advantage of the solvent method is that thermal decomposition of drugs and carriers associated with the fusion method can be avoided. The disadvantages include the higher cost of preparation, the use of large quantities of solvent and the difficulty in complete removal of solvent, the possible adverse effect of residual solvent, the selection of a common volatile solvent, the difficulty of reproducing crystal forms, and the inability to attain a supersaturation of the solute in the solid system unless the system goes through a highly viscous phase.

Supercritical Fluid Process

Supercritical CO₂ is a good solvent for water-insoluble as well as water-soluble compounds under suitable conditions of temperature and pressure. Therefore, supercritical CO₂ has potential as an alternative for conventional organic solvents used in solvent-based processes for forming solid dispersions due to its favorable properties of being nontoxic and inexpensive. The process developed by Ferro Corporation (14) consists of the following steps: 1) charging the bioactive material and suitable polymer into the autoclave; 2) addition of supercritical CO₂ under precise conditions of temperature and pressure, that causes polymer to swell; 3) mechanical stirring in the autoclave; and 4), rapid depressurization of the autoclave vessel through a computer-controlled orifice to obtain desired particle size. The temperature conditions used in this process are fairly mild (35–75°C), which allows handling of heat sensitive biomolecules, such as enzymes and proteins.

CLASSIFICATION OF SOLID DISPERSIONS

Chiou and Riegelman (2) classified solid dispersions into the following six representative types: 1) simple eutectic mixtures; 2) solid solutions; 3) glass solutions and

glass suspensions; 4) amorphous precipitations in a crystalline carrier; 5) compound or complex formation; and 6) combinations of the previous five types. Many techniques have been used to characterize the physical nature of solid dispersions. These include thermal analysis (e.g., cooling-curve, thaw-melt, differential scanning calorimetry and x-ray diffraction, microscopic, spectroscopic, dissolution rate, and thermodynamic methods) Usually, a combination of two or more methods is required to obtain a complete picture of the solid dispersion system.

Simple Eutectic Mixtures

These are prepared by rapid solidification of the fused melt of two components that show complete liquid miscibility but negligible solid–solid solubility. Thermodynamically, such a system is an intimately blended physical mixture of its two crystalline components. Thus, the x-ray diffraction pattern of a eutectic constitutes an additive composite of the two components. A phase diagram of a two-component system is shown in Fig. 1. Examples of this type include phenacetin-phenobarbital (15), chloramphenicol-urea (2), griseofulvin-succinic acid (16), paracetamol-urea, and the dispersions of griseofulvin and tolbutamide in polyethylene glycol-(PEG-2000; 17).

Solid Solutions

In a solid solution, the two components crystallize together in a homogeneous one-phase system. The particle size of

Fig. 1 Simple binary-phase diagram with eutectic formation. T_A is melting point of pure A; T_B is melting point of pure B; and E is eutectic point.

Fig. 2 A phase diagram of continuous solid solution for a binary system A and B.

the drug in the solid solution is reduced to its molecular size. Thus, a solid solution can achieve a faster dissolution rate than the corresponding eutectic mixture.

Solid solutions can be classified by two methods. According to the extent of miscibility of the two components, they may be classified as continuous or discontinuous. In continuous solid solutions, the two components are miscible in the solid state in all proportions. Typical phase diagrams of continuous and discontinuous solid solutions are shown in Figs. 2 and 3, respectively. Discontinuous solid solutions exist at extremes of composition. In general, some solid-state solubility can be expected for all two-component systems.

According to the criterion of molecular size of the two components, the solid solutions are classified as substitutional or interstitial. In the substitutional type, the solute molecule substitutes for the solvent molecule in the crystal lattice (Fig. 4). The molecular size of the two components should not differ by more than 15%. This class is represented by solid solutions of p-dibromobenzene-p-chlorobromobenzene, anthracene-acenaphthene, and ammonium and potassium thiocyanate.

An interstitial solid solution is obtained when the solute (guest) molecule occupies the interstitial space (Fig. 4) in the solvent (host) lattice. For this to occur, the solute molecule diameter should be less than 0.59 times that of the solvent molecule; therefore, the volume of the solute molecule should be less than 20% of the solvent molecule. Owing to their large molecular size, polymers favor the

Fig. 3 A typical phase diagram of a discontinuous solid solution for a binary system A and B; α and β are regions of solid solution formation.

formation of interstitial solid solutions. Examples of this type include solid solutions of digitoxin, methyltestosterone, prednisolone acetate, and hydrocortisone acetate in the matrix of PEG-6000. They all exhibit a fast rate of dissolution.

Fig. 4 Schematic representation of substitutional and interstitial solid solutions. Dark symbols represent solute atoms or molecules; open symbols indicate solvent atoms or molecules.

Fig. 5 Volume changes associated with cooling of a melt: T_g is the glass transition temperature and T_f is the melting point of the material.

Glass Solutions and Suspensions

A glass solution is a homogeneous glassy system in which a solute dissolves in the glassy carrier. A glass suspension refers to a mixture in which precipitated particles are suspended in a glassy solvent. The glassy state is characterized by transparency and brittleness below the glass transition temperature. Glasses do not have sharp melting points. Instead, they soften progressively on heating. The lattice energy, which represents a barrier to rapid dissolution, is much lower in glass solutions than in solid solutions. Fig. 5 shows the volume changes associated with glass formation when a melt is cooled down. Examples of carriers that form glass solutions and suspensions include citric acid, sugars such as dextrose, sucrose, and galactose, PVP, urea, and PEG.

Amorphous Precipitations in a Crystalline Carrier

This type of solid dispersion is distinguished from a simple eutectic mixture by the fact that the drug is precipitated out in an amorphous form. In a simple eutectic mixture, the drug is precipitated out in a crystalline form. An example of this is the precipitation of sulfathiazole in the amorphous form in crystalline urea (3). It is postulated that a drug with a propensity to supercooling has more tendency to solidify as an amorphous form in the presence of a carrier.

Fig. 6 Quinine-phenobarbital system, showing molecular compound formation. (Reproduced from Ref. 15. Copyright the American Pharmaceutical Association.)

Compound or Complex Formation

When two substances form a molecular compound, it usually gives rise to a maximum in the phase diagram. An example of this is the quinine-phenobarbital system (15) shown in Fig. 6. It is difficult to generalize the influence of complex formation on dissolution. A complex between digoxin and hydroquinone exhibited a high dissolution rate (16), whereas the insoluble complex between phenobarbital and PEG was shown to reduce both the rates of dissolution and the permeation of phenobarbital through everted rat gut (17).

MECHANISM OF INCREASED DISSOLUTION RATE

The enhancement in dissolution rate as a result of solid dispersion formation, relative to pure drug, varies from as high as 400-fold (18) to less than twofold. Corrigan (19) reviewed the current understanding of the mechanism of release from solid dispersions. The increase in dissolution rate for solid dispersions can be attributed to a number of factors. It is very difficult to show experimentally that any one particular factor is more important than another. The main reasons postulated for the observed improvements in dissolution of these systems are as follows:

1. Reduction of particle size. In the case of glass, solid solutions, and amorphous dispersions, particle size is reduced to a minimum level. This can result in an enhanced dissolution rate due to an increase in both the surface area solubilization.

2. Solubilization effect. The carrier material, as it dissolves, may have a solubilization effect on the drug. This was shown to be the case for acetaminophen and chlorpropamide in urea, as well as for numerous other drugs (20).
3. Wetability and dispersibility. The carrier material may also have an enhancing effect on the wetability and dispersibility of the drug in the dissolution media. This should retard any agglomeration or aggregation of the particles, which can slow the dissolution process.
4. Metastable forms. Formation of metastable dispersions with reduced lattice energy would result in faster dissolution rates. It was found that the activation energies for dissolution for furosemide was 17 kcal per mol, whereas that for 1:2 furosemide: PVP coprecipitate was only 7.3 kcal per mol (21).

RECENT ADVANCES

Serajuddin (22) reviewed recent advances in solid dispersion technology with particular emphasis on self-emulsifying systems. The advances in filling solid dispersion directly into hard gelatin capsules and availability of surface active and self-emulsifying carriers have renewed interest in commercial development of drug products based on solid dispersion. For ease of manufacturing, the carrier must be amenable to liquid filling into hard gelatin capsules as melts. The melting temperatures of carriers should be such that the solutions do not exceed approximately 70°C, which is the maximum acceptable temperature for hard gelatin capsule melts. Two such surface-active carriers that are being explored in solid dispersions for the bioavailability enhancement are Gelucire 44/14 (Gattfosse Corp, France) and Vitamin E TPGS NF (Eastman, Kingsport, TN). Gelucire 44/14 is a mixture of glyceryl and PEG-1500 esters of long chain fatty acids (lauryl macroglycerides). The suffixes 44 and 14 refer to its melting point and HLB value respectively. Serajuddin et al. also has shown that appropriate combinations of polysorbate 80 and PEG yield self-emulsifying systems.

SUSTAINED-RELEASE SOLID DISPERSIONS

More recently, the concept of solid dispersions has been explored using insoluble carrier materials. These systems are suitable for formulating sustained-release dosage forms. Hasegawa et al. (23, 24) prepared sustained-release

dosage forms of nifedipine by forming solid dispersions with anionic polymers, such as hydroxypropylmethyl cellulose phthalate and methacrylic acid-methacrylic acid methyl ester copolymers. Nifedipine in these solid dispersions was amorphous and was practically insoluble in gastric fluid (pH 1.2). However, it dissolved rapidly in intestinal fluid (pH 6.8) and showed a supersaturation phenomenon. These solid dispersions provided sustained absorption of nifedipine in beagle dogs with good availability after oral administration. Stability studies indicated that these dispersions were stable for at least 6 months under accelerated conditions. Similar dispersions of digoxin and dipyridamole (25) also showed delayed absorption with good bioavailability. Moreover, the chemical stability of digoxin in acidic medium was improved.

Fassihi et al. (26) used a combination of hydrophilic and lipophilic polymers to control the release rate. Thus, solid dispersions of theophylline were prepared by the fusion method using various ratios of PEG-6000, ethyl cellulose, and acrylic/methacrylic esters.

Takahashi et al. (27) showed that the coprecipitates of cationic water-soluble drugs (e.g., thioridazine hydrochloride), with pectin can be used as sustained-release preparations.

Controlled-release formulations of acetaminophen, aminopyrine, chlorpheniramine maleate, and salicylic acid that use Eudragit RSPM as a water-insoluble carrier, prepared by the solvent method, have been reported (28). A novel approach that uses a less soluble derivative of the drug as a carrier was used by Yang and Swarbrick (29) to prepare sustained-release solid dispersions of dapsone.

SELECTION OF A CARRIER

The properties of the carrier have a major influence on the dissolution characteristics of the dispersed drug. A carrier should meet the following criteria to be suitable for increasing the dissolution rate of a drug: 1) be freely water-soluble with intrinsic rapid dissolution properties; 2) be nontoxic and pharmacologically inert; 3) be heat stable with a low melting point for the melt method; 4) be soluble in a variety of solvents and pass through a vitreous state upon solvent evaporation for the solvent method; 5) be able to, preferably, increase the aqueous solubility of the drug; and 6) be chemically compatible with the drug and not form a strongly bonded complex with the drug.

Table 1 Materials used as carriers for solid dispersions

Sugars: Dextrose, sucrose, galactose, sorbitol, maltose, xylitol, mannitol, lactose
Acids: Citric acid, succinic acid
Polymeric materials: Povidone (PVP), polyethylene glycols (PEG), hydroxypropyl-methylcellulose, methylcellulose, hydroxyethylcellulose, cyclodextrins, hydroxypropylcellulose, pectin, galactomannan
Insoluble or enteric polymers: Hydroxypropylmethylcellulose phthalate, Eudragit L-100, Eudragit S-100, Eudragit RL, Eudragit RS
Surfactants: Polyoxyethylene stearate, Renex, Poloxamer 188, Texafor AIP, deoxycholic acid, Tweens, Spans
Miscellaneous: Pentaerythritol, pentaerythrityltetracetate, urea, urethane, hydroxyalkylxanthins.

(Adapted from Ref. 19).

Table 1 shows a list of materials used as carriers for solid dispersion formation. An excellent review of many of these carriers is included in an article by Ford (30). Enteric polymers are useful in the formation of solid dispersions of acid labile drugs. In some cases, a combination of carriers is more useful.

ADVANTAGES AND DISADVANTAGES OF SOLID DISPERSIONS

Among the advantages of solid dispersions are the rapid dissolution rates that result in an increase in the rate and extent of the absorption of the drug, and a reduction in presystemic metabolism. This latter advantage may occur due to saturation of the enzyme responsible for biotransformation of the drug, as in the case of 17- β -estradiol (31); or inhibition of the enzyme by the carrier, as in the case of morphine-tristearin dispersion (32). Both can lead to the need for lower doses of the drug. Other advantages include transformation of the liquid form of the drug into a solid form (e.g., clofibrate and benzoyl benzoate can be incorporated into PEG-6000 to give a solid (33), avoidance of polymorphic changes and thereby bioavailability problems, (as in the case of nabilone and PVP dispersion (34), and protection of certain drugs by PEGs (e.g., cardiac glycosides) against decomposition by saliva to allow buccal absorption (35).

The major disadvantages of solid dispersions are related to their instability. Several systems have shown changes in crystallinity and a decrease in dissolution rate with aging. The crystallization of ritonavir from the

supersaturated solution in a solid dispersion system was responsible for the withdrawal of the ritonavir capsule (Norvir, Abbott) from the market (36). Moisture and temperature have more of a deteriorating effect on solid dispersions than on physical mixtures. Some solid dispersions may not lend themselves to easy handling because of tackiness.

REVIEW OF IN VIVO STUDIES

Several examples of in vivo performance of solid dispersions have been published. The in vivo performance of solid dispersion systems containing sulfathiazole-urea, chloramphenicol-urea, reserpine-bile acids, and griseofulvin-PEGs were reviewed by Chiou and Riegelman (2). Some other representative examples are summarized below:

1. Nifedipine. Solid dispersions of nifedipine with PVP (37) and enteric polymers (23, 24) were evaluated in dogs and humans. PVP dispersions showed rapid absorption with a threefold increase in bioavailability when compared to physical mixtures. Sustained blood levels were obtained from solid dispersions with enteric polymers.
2. Acetaminophen. The effect of aging of the solid dispersion of acetaminophen in PEG-20,000 on human bioavailability was studied (38). It was found that the bioavailability of the sample stored at room temperature for 9 months decreased. This was due to an increase in the crystallinity of the drug.
3. Phenytoin. Solid dispersions of phenytoin in PEG-4000 (39), PEG-6000 (40), and PVP (41) were evaluated in vivo. The total areas under blood concentration curve (AUC) after oral administration to human volunteers were fourfold greater from a 1:10 PEG-4000 dispersion and 2.7-fold greater from a physical mixture than from phenytoin crystals. PEG-6000 dispersions (40% drug) were examined in mixed-breed dogs and compared with phenytoin sodium. Although phenytoin sodium dissolved several times faster in vitro than the solid dispersion of phenytoin, the two preparations were found to be bioequivalent. Sekikawa et al. (41) studied absorption of phenytoin in humans from PVP dispersions. The extent of bioavailability of phenytoin in phenytoin-PVP coprecipitate was 1.54 times greater than that of phenytoin alone.
4. Nitrofurantoin. Nitrofurantoin dispersed in PVP, PEG, and mannitol was evaluated in humans by studying cumulative urinary excretion of the drug (42). A linear

correlation was found between the amount of nitrofurantoin dissolved in acidic medium after 30 and 90 minutes and the cumulative amount of unchanged drug excreted after 12 h. The bioavailability relative to pure drug was 239% for a 1:4 PVP dispersion, 190% for a 1:4 PEG-6000 dispersion and 150% for a 1:10 mannitol dispersion. Stoll et al. (43) studied the absorption characteristics of various nitrofurantoin and nitrofurantoin-deoxycholic acid preparations. The 1:5 (w/w) nitrofurantoin-deoxycholic acid dispersion showed significant increases in both the rate and extent of absorption when compared with either the drug alone or the physical mixture.

5. Dicumarol. Sekikawa et al. (11) used the rabbit as a model to evaluate the performance of solid dispersions of dicumarol in PVP and β -cyclodextrin. Peak levels of the drug were observed at 4–6 h postadministration in the cases of the solid dispersion systems. In the case of dicumarol crystal powder, peak levels were observed at 2 to 12 hours postadministration. Average AUC values (0–48 h) of dicumarol following the administration of the dicumarol-PVP solid dispersion systems were 3.31 times (coevaporation method) and 1.54 times (freeze-drying method) that of control. The corresponding numbers for β -cyclodextrin dispersions were 2.18 and 1.72.
6. HIV Protease Inhibitor. The bioavailability of ritonavir (Norvir, Abbott), an HIV protease inhibitor, was enhanced by formulation as a solid dispersion in a mixture of surface active carrier, such as Gelucire 50/13, polysorbate 80, and polyoxyl-35 castor oil.

FUTURE OF SOLID DISPERSIONS

In spite of tremendous research activity in the area of solid dispersion since its introduction to pharmaceutical applications in 1961, only a few systems, such as Gris-PEG (Sandoz), a griseofulvin-PEG solid dispersion, Cesamet (Lilly), a nabilone-PVP solid dispersion, Sporanox capsules (Janssen), an itraconazole-HPMC solid dispersion, and Norvir capsules (Abbott), are identified as such in the market place. Most likely many others are utilized but masked as formulation methods. Perhaps the limited commercial utilization of the concept stems in part from the instability of solid dispersions on aging and the need for a high content of carrier, which might restrict its use to very potent drugs for physical and economic reasons. Nevertheless, solid dispersions have great potential both for increasing the bioavailability of drugs and for developing controlled-release preparations.

In regard to manufacturing considerations, the problem of total solvent removal in dispersions prepared by the solvent method needs to be addressed. The method created by Hasegawa et al. (23), which involves spray coating of nonpareils or any other inert core with drug-carrier solution, provides a one-step process of achieving a multiunit dosage form of solid dispersions. With particle-coating equipment now commercially available (44), this process has a promising future, as exemplified by commercial success of Sporanox capsules manufactured by this technique (45).

The problem of instability of the supersaturated state upon dissolution, which results in a stable form, has been dealt with by addition of a retarding agent. Methyl cellulose was used as a retarding agent in dispersions of indomethacin and flufenamic acid in PVP (46, 47). Computer optimization of such compositions, as described by Takayama, et al. (47), will certainly be of great value. More work is needed in these areas.

Novel formulating methods can provide cleaner manufacturing conditions. For example, Walker et al. (48) demonstrated the feasibility of liquid-filling gelatin capsules with the liquid melt and avoiding grinding-induced changes in crystallinity. This would be a very attractive feature for potent drug candidates. Exploration for new carrier systems will certainly continue. The most commonly used carriers are polymers, such as PVP and PEG. Recently lipids (49), freeze-dried milk (50), and self-emulsifying agents (22) have been used as carriers. Finally, the emergence of considerable research on novel drug-delivery systems may provide the greatest impetus for increased use of solid dispersions. Valuable preliminary studies of the use of solid dispersions to provide sustained- or controlled-release of drugs (23–27) have been reported. A U.S. patent (51) describes a method of preparation for a controlled release preparation of cyclosporine in biodegradable polymer, such as poly-D,L-lactide or a blend of poly-D,L-lactide and poly-D,L-lactide-co-glycolide. More and more commercial applications are expected in this area.

COOLING PROCESSES AND CONGEALING

Richard Turton

West Virginia University, Morgantown, West Virginia, U.S.A.

Xiu Xiu Cheng

Andrx Pharmaceuticals, Inc., Fort Lauderdale, Florida, U.S.A.

INTRODUCTION

The purpose of this article is to introduce the major concepts and applications of cooling and congealing processes in the pharmaceutical industry. A cooling and congealing process must follow any process involving a melt. The melt-congealing technique has been practiced in the manufacture of wax-based suppositories for over 100 years. New applications have evolved quickly in the last 40 years to meet the increasing need for improving the solubility and consequent bioavailability of poorly water-soluble drugs and making modified-release drug products. Solid dispersions, matrix tablets, and coated drug-laden beads are some common examples. One of the methods of preparing solid dispersions is melt-congealing. The basic concept and process required to form solid dispersions of poorly water-soluble drugs in solid matrices is attributable to the work of Sekiguchi and Obi in 1961 (1). They melted a sulphathiazole-urea mixture of eutectic composition at above its eutectic temperature, solidified the dispersion in an ice bath, and pulverized it into a powder. A modification of the process involves spray-congealing from a modified spray-dryer onto coated metal surfaces and has been used for dispersions containing mannitol (2). Hot-melt coating and granulation processes have also been used in the development of wax-coated or wax-based matrix sustained-release products.

In this article, typical systems that make use of melt-congealing processes, the equipment and important operating variables used, typical matrix substrate materials, important processing considerations, and the advantages and disadvantages of using these systems are addressed.

PRINCIPAL CONCEPTS

Many review articles and many more research studies have been written on the use of systems involving the congealing and cooling of solid mixtures or solutions to produce both fast-release and sustained-release dosage

forms. There are many reasons for using such systems. An overview of the uses of congealed solids in the production of pharmaceutical dosage forms is shown in Fig. 1. From this figure we can see that the congealable solid may play an active role in controlling the rate of release of the active ingredient or may just be a cosmetic agent.

When the role of the congealable solid is to retard the rate at which drug is released, the congealed solid may be used as an overcoat on a substrate containing the active (e.g., a drug-laden nonpareil). In this case, typical coating equipment such as fluidized beds and perforated pans can be used. Alternatively, the congealable solid may be part of a drug-containing matrix that is permeable to gastric fluids or is erodable. In this case, the dosage form may be produced using a variety of methods, e.g., spray-congealing of a liquid (melt), granulation using a high-shear granulator, extrusion using a twin screw extruder, etc.

When the object is to increase the rate of drug dissolution, the drug is usually dispersed in a matrix composed of the congealable solid. The first step in this process is to form a solution or well-mixed dispersion of drug in the molten carrier. Subsequently, this mixture is cooled and solidified, and the resulting solid forms a solid matrix in which drug is very finely dispersed. This method can yield a solid dispersion in which the drug is dispersed at a molecular level, and the rate of dissolution of even very poorly soluble drugs can be enhanced significantly owing to the increase in exposed drug surface area. Spray-congealing and melt-granulation processes are often used to produce this type of product.

The use of a congealable solid as a taste-masking agent or for cosmetic purposes is also reported in the literature. Cosmetic uses usually involve a coating process, whereas taste-masking can be implemented using both overcoating and drug-carrier matrix formation.

Formation of Dispersions of Drugs in Carriers

One important reason for forming a drug dispersion in a carrier is to increase solubility of poorly water-soluble

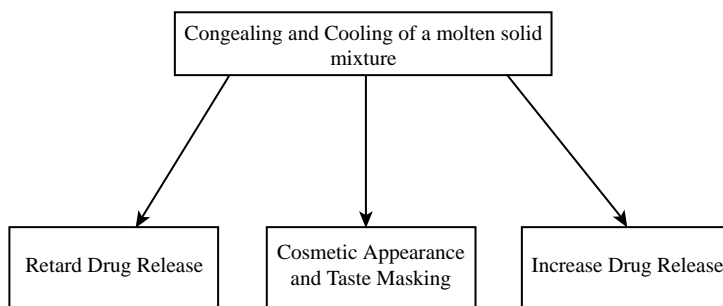

Fig. 1 General overview of uses of congealed solids in pharmaceutical dosage forms.

drugs. The dispersion of the active ingredient in a suitable matrix or carrier provides a large, exposed, drug surface area that compensates for the poor water solubility of the drug. In principle, a large surface area can be provided by fine milling (micronization) of the drug and subsequent dispersion of the drug powder in a carrier. However, owing to the cohesive nature of very fine particles, the effective dispersion of the micronized drug into the carrier can be problematic, resulting in maldistribution of the drug and consequent poor release characteristics. Despite this disadvantage, the rapid cooling and “freezing” of liquid carriers containing dispersions or slurries of fine drug powder are practiced, as is the melt granulation of a drug with a molten substrate. Another approach is to dissolve the drug into a liquid carrier and then to rapidly cool and congeal the mixture. The resulting solid will contain drug particles dispersed at the molecular or near molecular level within the solidified matrix carrier. Clearly, for this process to be effective, it is preferable that the drug is soluble in the molten carrier. A significant increase in drug-dissolution rate can then be achieved. It should be pointed out that the properties of both the drug and carrier, their interactions, the rate of cooling and congealing, and the conditions of storing the final dosage form all play an important role in the performance of the final product. All these factors are addressed in the sections below. The phase diagrams describing the behavior of different binary drug-carrier systems are reviewed in the following section.

Phase Diagrams

As an example of a liquid-solid phase diagram, we consider the salol-thymol system shown in Fig. 2 (3). This system represents a simple eutectic in which the two components are totally miscible in the liquid phase and totally immiscible in the solid phase. From Fig. 2, we see that the diagram is divided into four zones. In zone 1, both

components exist as a liquid solution; in zones 2 and 3, both components exist as a liquid solution in equilibrium with the other component in the solid form. In zone 4, both components exist as solids. Each zone boundary represents an equilibrium line. For example, consider a salol-thymol system containing 64 wt% thymol at a temperature of 48°C. This is denoted by point A on the diagram. If we slowly cool this solution (at constant pressure), then at approximately 30°C (point B) we will see that the first crystal of pure, solid thymol forms. If we cool the mixture more, pure thymol will continue to crystallize, and the resulting liquid solution becomes depleted of thymol. At approximately 20°C, we are at point C, and the resulting solution, which is in equilibrium with pure thymol (point D), has a composition of 48 wt% thymol, shown by point E. Continued cooling brings us to point F, where the solution composition is shown by point G. This is the eutectic composition. Further cooling beyond point G to point H, for example, gives rise to the formation of two solid phases, namely, pure salol (point I) and pure thymol

Fig. 2 Phase diagram for the thymol-salol system. (From Ref. 30.)

(point J). If we were to repeat this cooling process but start with a liquid solution with a composition to the left of the eutectic point (G), then the phase transformations would be similar except that pure salol would crystallize, and the remaining solution would become depleted in salol. The composition of this solution would move to the right and would eventually reach the eutectic composition G when the temperature reached 13°C. Further cooling would produce two solid phases of pure salol and pure thymol. The eutectic point (G) is the only condition at which a liquid solution of salol and thymol is in equilibrium with both pure solid thymol and pure solid salol. Recalling the Gibbs phase rule for systems in equilibrium:

$$F = 2 + C - P \quad (1)$$

For our salol–thymol system at the eutectic, we have three phases ($P = 3$) and two components ($C = 2$); therefore, we have only one degree of freedom ($F = 1$). For the system considered in Fig. 2, the pressure of the system is fixed, thus accounting for the single degree of freedom. Therefore, for such a system at a known pressure, there only exists a single temperature at which the eutectic can form, which is 13°C for this case.

The salol–thymol system presented is an example of a system that yields a solid dispersion when a solution is cooled rapidly. This solid dispersion consists of an intimate crystalline dispersion or mixture of one component distributed in the other. The uniformity of the dispersion of the two solid phases in each other is important to the dissolution behavior of the system. With all other factors being equal, the more uniform the dispersion, the faster and more reproducible will be the dissolution. It should be noted that the information given in Fig. 2 is accurate only if the system is in equilibrium. The conditions prevailing in any production process will most often fall short of providing equilibrium. Indeed, the idea of rapidly cooling a solution will inevitably lead to temperature and concentration gradients within the liquid and result in significantly different local congealing rates. The cooling and thickening (increase in viscosity) of the liquid act to trap crystals within the matrix and tend to minimize the diffusion and migration within the matrix. This has an added effect of limiting aggregation of the crystals and maintaining the drug in a well-dispersed form. Therefore, it can be seen that the design of the congealing device or equipment is of significant importance in the production of well-controlled dosage forms utilizing this technology. From Fig. 2, it is clear that rapid cooling of a solution with the eutectic composition can give rise to a well-dispersed solid dispersion and requires the least amount of cooling duty. However, the drug-loading in the

final dosage form, along with other factors, often precludes the congealing of eutectic mixtures in favor of other liquid compositions. Solid dispersions that exhibit negligible mutual solubility in the solid phase giving rise to eutectic mixtures, as previously described, are uncommon. Examples are given by Ford (4) and include paracetamol-urea, by Goldberg et al. (5), griseofulvin–succinic acid, by Goldberg et al. (6), and griseofulvin–PEG 4000 and 6000, by Chiou (7).

Another form of solid dispersion is the solid solution. The phase diagram for two materials (X and Y) that give rise to solid solutions is different from that previously discussed; an example of such a system is shown in Fig. 3 (8). This diagram is an example of a system in which both components (drug and carrier) have a limited solubility in each other in the solid phase. Consider the cooling of a liquid with composition and temperature given by point A. As the liquid is cooled, it will reach a point B on the equilibrium line. At this point, the first crystal of solid phase will be formed. The composition of this solid phase (α) is given by point C, and comprises a solid mixture of both X and Y. The composition of the liquid in equilibrium with this solid is given by point B. As the cooling continues, more solid will crystallize out of the solution, and the compositions of both the liquid solution and the solid change during this process. At point D, the eutectic temperature is reached. Cooling below the eutectic temperature causes two solid phases to crystallize from solution. The compositions of the two phases are given by the endpoints of the constant temperature line (points E and F); these two solid phases are in equilibrium with the remaining eutectic solution. Just as in the simple system illustrated in Fig. 2, there is a single eutectic

Fig. 3 Phase diagram for two components, X and Y, which are miscible in the liquid phase and mutually soluble in the solid phase. (From Ref. 8.)

temperature at which liquid and both solid phases can coexist. However, unlike the simple system, the composition of the solid phases will change with temperature.

Other structures may exist owing to interactions between the drug and carriers. Ford (4) addresses the following systems: glass solutions and glass suspensions, amorphous precipitations in a crystalline carrier, compound or complex formation, and combinations of these systems.

COMMON CARRIERS/EXCIPIENTS

Desirable Properties of Carriers

The properties of the congealed carriers clearly control the release of the drug from the dosage form. Reviews by Ford (4) and Achanta and associates (9) have been carried out in which the carrier properties are compared and contrasted, and these are summarized here. For hot-melt coatings, Achanta and associates (9) give the following ideal coating material characteristics:

1. It should be stable below 200°C.
2. It should have a melting point in the range of 75–80°C.
3. It should possess a narrow melting-point range and should not undergo softening before melting.
4. Its thermal behavior in the range of 30–200°C should be independent of its thermal history, method of preparation, and method of storage.
5. No crystal modifications should occur when it is exposed to temperatures up to 200°C.
6. It should be stable when subjected to thermal cycling.
7. It should possess a low melt viscosity to facilitate flow and spray formation.

These characteristics essentially ensure that the coating material is stable under typical coating conditions (items 4–6), that unwanted agglomeration is minimized (item 3); that it can be easily sprayed (item 7); and that operating temperatures are moderate so as to minimize drug degradation (items 1 and 2). In addition to these attributes, the coating material should clearly not interact with or adversely affect the drug's bioavailability.

For the formation of solid dispersions by congealing a melt of poorly water-soluble drug and carrier, Ford (4) recommends the following "ideal" characteristics for the substrate/carrier material:

1. It should be freely water soluble with intrinsic rapid dissolution properties
2. It should be nontoxic.

3. It should be chemically, physically, and thermally stable, with a low melting point. On solidification, it should crystallize rapidly and maintain the drug as a fine crystalline dispersion. The carrier and drug should be miscible in the liquid to avoid irregular crystallization and subsequent variability in dissolution rate.
4. The carrier should ideally increase the water solubility of the drug.
5. The carrier should not form stable complexes with the drug that would retard dissolution.
6. The carrier should be pharmacologically inert.

These characteristics ensure that, on solidification, the drug will be well dispersed with a large surface area available for dissolution (item 3); that the carrier will not inhibit the dissolution process or effect the drug (items 1, and 3–5); and that the carrier is inert (items 1 and 6). Above all, all of the carriers/excipients should have necessary regulatory approval for pharmaceutical use.

The carriers used in the production of sustained-release matrix tablets of water-soluble drugs by melt-congealing share some of the characteristics of carriers used for hot-melt coating and solid dispersion preparations. However, most of them have melting points in the range of 50–85°C.

Suitable Commercial Excipients

In general, an ideal carrier or coating material will not be available, and some compromises will have to be made. Perhaps some of the most important and common problems associated with the use of these carriers are their tendency to form crystalline polymorphs during the congealing process. In addition, there are subsequent changes in dissolution characteristics that occur on storage caused by changes in crystalline structure. The problems of changes in crystallinity are addressed later.

Congealed solids commonly used as carriers and coating materials have been summarized by Ford (4) and Achanta (9) and are:

Citric and Succinic Acids: Citric acid was used in solid dispersion preparations because of its high water solubility and its capability of glass formation. The monohydrate melts at approximately 100°C, whereas the anhydrous form melts at approximately 153°C. Drug degradation is quite probable at the higher temperature because the release of the water of hydration from the monohydrate form can affect moisture-sensitive drugs.

Bile Acids, Sterols, and Steryl Esters: Many of these compounds have high melting points, making them unsuitable for melt applications. Exceptions are the salicylic acid–cholic acid system formed by a melt-granulation technique reported by Froemming and

Vetter (10). The system provided a sustained release in acid media (pH 1–3.5).

Sugars: Again, many sugars have excessive melting points to be considered viable candidates for melt-congealing processes. However, the use of a few of the sugars has been reported in the literature. The application of zylitol in the formulation of the diuretic hydrochlorothiazide was demonstrated by Sirenus and coworkers (11). Hirasawa et al. (12) prepared naproxen solid dispersions by melting and rapid cooling with liquid nitrogen, using lactose as a carrier. Danjo and associates (13) prepared ethenzamide solid dispersions using sugars such as sucrose, maltose, galactose, and mannitol as carriers by melting and rapid cooling with liquid nitrogen. It was found that solid dispersions made with amorphous sucrose were more stable than those made with other sugars.

Urea: Urea has been used both to form solid dispersions by the cooling of urea–drug mixtures and to directly coat drug-laden particles in melt-coating operations. It has a melting point of approximately 130°C and is highly soluble in water. A variety of urea–drug dispersions obtained from melt processes have been reported in the literature, and these include aspirin, paracetamol, phenobarbitone, and tolbutamide. One disadvantage of using molten urea is its instability, resulting in the evolution of ammonia.

Polyethylene Glycols (PEG): These represent one of the most common materials used in the formation of solid dispersions from melts. The family of PEG polymers has molecular weights ranging from a few hundred to a few hundred thousand. Typical values for solid dispersions are 2000–20,000. Examples of solid dispersions of griseofulvin, indomethacin, and tolbutamide in PEG formed by the coagulation of PEG–drug melts have been reported extensively in the literature. PEG has the added advantage of increasing the water solubility of many drugs. This, along with its availability in many molecular-weight forms, makes it a popular material for the formation of solid dispersions.

Poly (Ethylene Oxide) (PEO) Polymers: In the same family as PEG, but having higher molecular weights are POLYOX[®] resins, which are water-soluble polymers. Because of their low melting point and unique swelling properties, coupled with the controlled rate of dissolution, POLYOX resins have been used to make sustained-release formulations by hot-melt extrusion (14).

Hydroxypropyl Methylcellulose (HPMC): Suzuki and Sunada (15a, 15b) report the production of solid dispersions prepared with nicotinamide and HPMC as combined carriers using nifedipine and nitrendipine as model drugs. Their solid dispersions were obtained using the fusion method. After both the drug and HPMC were dissolved in

the liquid melt of nicotinamide at 140°C, the fused mixture was cooled to solidify it.

Natural and Synthetic Waxes: The most common natural wax used as a congealing agent is carnauba wax derived from the wax palm or carnauba (*Copernicia cerifera*) found in Brazil. The major constituents of this wax are aliphatic esters, hydroxy esters, and methoxycinnamic and hydroxycinnamic aliphatic diesters. This is one of the hardest and highest-melting-point natural waxes (m.p. 82–85°C). It is used both as a coating agent, (9, 16) and as solid dispersion carrier (4, 17). Other natural waxes used in congealing applications include paraffin waxes and beeswax (18, 19). Synthetic waxes, such as stearic acid and stearyl alcohol, are often used in the formulation of sustained-release wax matrices by melt-congealing processes (20).

Hydrogenated Vegetable Oils: These primarily consist of the family of stearines. Hydrogenated castor oil (Cutina HR[®]) has been used as a wax matrix material both in melt-granulation (21) and spray-congealing processes (22).

Glycerides and Polyglycolized Glycerides: Most common carriers used in the preparation of sustained-release wax matrix formulations are glycerides and polyglycolized glycerides. There are several commercial products on the market, for example, Compritol 888 ATO (glyceryl behenate), Myverol 18092 (distilled monolinoleate), Myverol 18-99 (distilled monooleate), and Myveplex 600 (glycerol monostearate). They have been used as hydrophobic coatings (19), spray-congealing agents (11, 23), and retardant materials to form wax matrices (24).

Other Polymers and Excipients: Some other excipients have been used in the preparations of solid dispersions and sustained-release wax matrices by melt-congealing processes. The most common examples are the family of ethylacrylate and methylmethacrylate copolymers (Eudragits). Although these agents are generally not suitable for melt formation, they have been used successfully to modify the release of products formed by melt processes. For example, Miyagawa et al. (25) used both hydropropylcellulose and Eudragit L-100 to modify the release characteristics of diclofenac sodium from granules formed by the melt extrusion of a mixture of drug, release agents, and carnauba wax. The application of these excipients has also been demonstrated by Emori and colleagues (26).

IMPORTANT PROCESSES AND EQUIPMENT

Coating Processes

When the active ingredient is contained in an inert core material, for example, granulated with sucrose, and a

sustained-release coating of a congealable material is desired, then the equipment of choice is often the fluidized bed using a top-spray configuration (27). However, a bottom-spray configuration using a Wurster column insert can also be used. The fluidized bed offers the unique advantage of very high rates of heat and mass transfer from the molten solid to the particles to be encapsulated. Important processing variables are the temperature of the bed, temperature and flow rate of fluidizing air, temperature of the molten material and atomizing air; spray rate; and atomizing air pressure. According to Jones and Percel (28), the product temperature and droplet size of the molten material being sprayed (this is a function of atomization air pressure and spray rate) are the key variables. Special attention must also be given to the insulation of the spray nozzle within the bed to avoid remelting coated particles that come in contact with the nozzle during processing (9). The heat tracing of the lines containing the molten material is also imperative to avoid the solidification of coating material before reaching the nozzle. Jozwiakowski et al. (27) investigated the coating of a sugar-based granulation with a partially hydrogenated cottonseed oil (Durkee 07 Stearine, Durkee Industrial Foods) using a factorial experimental design. The melting point of this wax was 64°C, and it was found that excessive growth and rough coated surfaces were obtained when the bed temperature was held at 58°C. However, particles coated at bed temperatures of 54 and 50°C had uniform, smooth coated surfaces.

A novel fluidized-bed coating application that avoids the use of a spray nozzle for the delivery of the congealable solid additive was demonstrated by Kennedy and Niebergall (18, 19). They coated chlorpheniramine maleate (CPM)-loaded nonpareils with a variety of different waxes, including beeswax. The method of preparation involved loading a fluidized bed with both the nonpareils and the coating agent, both in powder form. The bed was then fluidized with heated air, the temperature of which was varied. The process consisted of four steps: 1) equipment warm-up, 2) preheating of substrate, 3) melting and spreading of the coating agent, and 4) cooling and subsequent solidification of the coating agent. Dissolution-release profiles for the nonpareils

coated with beeswax showed significant sustained-release characteristics. The coating of nonpareils from 10 to 35 mesh and particles up to 1 g are reported to be feasible.

Spray-Congealing Processes

The formation of drug dispersions within a congealed matrix is conveniently carried out in a spray-congealing apparatus. The process and important operating parameters for this type of equipment are addressed in detail by Killeen (29). The basic steps in the spray-congealing process are described in Fig. 4. First, the molten liquid, containing all the excipients, is fed to an atomizing nozzle. The atomized droplets then leave the nozzle and enter the cooling vessel or chamber, where they mix with chilled air. The droplets solidify and either fall to the bottom of the chamber or become entrained in the upward-moving airflow. The smaller particles that become entrained in the flow of air are separated from the air in a cyclone separator. The larger particles that settle to the bottom of the chamber are discharged. If necessary, the product can be size-separated as needed before further processing.

The atomizing nozzle may be one of four basic types: 1) dual-fluid, 2) single-fluid pressurized, 3) single-fluid disk or rotary, and 4) single-fluid ultrasonic. As with all congealing processes, the feed lines must be heat-traced to avoid unwanted solidification, and the nozzle should be insulated within the equipment to avoid the remelting of product coming in contact with it. For the best control of particle size and uniformity, the dual fluid or atomizing air nozzle is recommended. This nozzle can produce particles well below 50 μm , and because the airflow rate and pressure can be controlled separately, the size of the droplets can be controlled independently of the liquid flow rate. The air atomizing nozzles become problematic when the viscosity of the molten liquid is very high or the amount of solids loading in the melt is high. In these cases, the single-fluid nozzles are often preferred. Single-fluid pressurized (hydraulic) nozzles make use of the pressure of the fluid to cause atomization when flowing through the small orifice holes in the nozzle. These devices are suitable when the solids content of the melt is low and droplet size

Fig. 4 Subprocesses occurring during spray congealing. (From Ref. 29.)

is not too small (for example, not less than 100–200 μm). Disk or rotary atomizers consist of a disk connected to a rotating shaft onto which the molten liquid flows. The liquid is broken up into drops by the spinning motion of the disk that produces a thin, radial outward-moving droplet spray pattern. This gives rise to a collection chamber that is short and wide, which requires less headroom than for processes using hydraulic and air atomized nozzles. The size distribution of the product is controlled by the liquid feed rate and the speed of rotation of the disk. These types of nozzle can process molten liquids that are corrosive, heat-sensitive, and contain less than 20% solids. In processes that use either hydraulic or rotary nozzles, the rate of cooling of the drops is relatively slow, and the flow of cocurrent and/or countercurrent air in the cooling chamber is significantly greater than for air atomizing nozzle systems. The use of ultrasonic nozzles for the manufacture of congealed solid products is relatively new. This type of nozzle uses the movement of an oscillating plate vibrating at ultrasonic frequencies to break up a liquid stream fed to the surface of the plate. The droplets formed are generally very small (less than 30 μm) and are suitable for low liquid flow rates. Because the droplet formation process imparts little directed kinetic energy to the drops, the spray pattern is quite small and controlled. In a recent study, Rodriguez and associates (22) demonstrated the efficacy of using an ultrasonic nozzle to produce spray-congealed products of theophylline and fenbufen in wax matrices.

The cooling chamber design must allow for the disengagement of the solidified droplets from the cooling air stream while also allowing the droplets sufficient residence time to cool and solidify. For a given liquid feed rate and composition, the amount of cooling is fixed. This is because the heat removal is equal to the latent heat of solidification plus the sensible heat of cooling the product, both of which are fixed by the liquid feed rate. The finer the droplets that are produced, the slower the air velocity must be to allow for disengagement; however, heat transfer tends to be rapid for small drops. Therefore, because the flow of air is essentially fixed owing to the cooling duty, this leads to wider and shorter cooling vessels. For larger droplets, particle disengagement can take place at higher gas velocities. However, heat transfer is slower, and droplet residence time must be longer. This leads to narrower and taller cooling vessels. Countercurrent and cocurrent airflows are possible as are mixed airflow patterns; several other design considerations are discussed by Killeen (29). Other important product parameters such as molten liquid viscosity, surface tension, specific gravity, and solids concentration, and processing parameters such as air flow rate, flow patterns,

spray angle, spray impingement, and nozzle resistance to abrasion are also addressed in this reference. According to Yajima et al. (30), the key product variable for the successful production of a wax matrix containing clarithromycin that masked the bitter taste of this macrolide antibiotic was the congealing speed. The important process variables were the liquid feed rate and atomizer (rotary) wheel speed.

Granulation Processes

The mixing of drug powder into a wax matrix and the subsequent uniform dispersion of the drug within the matrix can be carried out using a variety of granulating techniques. Thies and Kleinebudde (31) describe a process by which a hygroscopic drug, sodium valproate, was dispersed in a meltable binder, glycerol monostearate, using a high-shear mixer. The high-shear mixer was modified by adding a temperature bath that surrounded the mixing bowl. The prescreened drug was first added to the bowl and preheated and mixed for 10 min. The binder (glycerol monostearate) was then added to the mixer, and the granulation process began. Because of the hygroscopic nature of the drug, all formulation-related activities were performed in atmospheres with a relative humidity of less than 40%. The solidification temperature of the drug–binder combination was approximately 35°C. This temperature was approximately 35°C lower than the pure binder owing to the addition of the drug. The resulting granules, in the size range of 4 mm–500 μm , were cooled to room temperature and used for analysis. The effects of several process variables on the properties of the granules were investigated. These variables included the amount of binder, the process temperature, the granulation (massing) time, and the speed of the impeller.

Evrard et al. (21) investigated the influence of the melting and rheological properties of the binder in high-shear mixer granulation processes. These researchers concluded that successful granule formation took place in high-shear mixers using a variety of low-melting-point binders (Compritrol® 888, Cutina® HR, and Precirol® ATO5) at temperatures below their melting points. The binder only needed to be softened to produce granules. The melting range of the binder and the effect of temperature on the binder viscosity influenced the rate at which granules grew during the particle-formation process.

Melt-Extrusion Processes

The hot-melt-extrusion process is a well-established unit operation in the polymer pelleting and compounding

Fig. 5 Schematic diagram of a twin-screw compounding extruder. (From Ref. 25.)

industry. The concept is to feed a polymer powder along with desired additives, such as fillers, dyes, and other polymers, and then subject them to a high temperature and very high-shear environment. The temperature causes the polymers to melt, and the high shearing action of the screw(s) causes the other additives to be intimately mixed and dispersed within the polymer melt. Both single-screw and twin-screw units are common; the latter is capable of producing much higher pressures than is the single-screw unit. A schematic diagram of a twin-screw extruder is shown in Fig. 5. The extruder consists of essentially seven regions: the powder supply window, the barrel, the screws, the die, the drive section, the cooling/heating unit, and the control panel.

Because the process of polymer-compounding is very similar to the dispersion of a drug in a congealable solid matrix, it is not surprising that hot-melt extrusion techniques have been applied to the production of wax matrix formulations. Miyagawa et al. (25) used a twin-screw compounding extruder to prepare granules of diclofenac sodium dispersed in a carnauba wax matrix. They cited the following advantages of using such a device:

High kneading and dispersing ability can be achieved within the unit independently of the physical and chemical properties of the excipients.

The temperature in each zone of the unit can be controlled accurately.

The unit demonstrates superior extruding capability.

Residence time of powders in the barrel is minimized, thus minimizing the product degradation.

The unit is easy to clean.

Zhang and McGinity (14) also demonstrated the use of this type of equipment to formulate a sustained-release tablet of chlorpheniramine maleate (CPM) dispersed in a wax matrix consisting of polyethylene oxide (PEO). The content uniformity of their extruded tablets was in the range of 99–101% of theoretical drug content, which for a low-dose drug such as CPM was considered very good.

For this application, the sustained-release profiles were significantly affected by the addition of polyethylene glycol (PEG). The release rates increased with increasing amounts of PEG. PEG was also found to significantly lower the required processing temperature and reduce the required torque needed to extrude the tablets. These investigators concluded that the hot-melt-extrusion process was suitable for the preparation of these sustained-release tablets and that significant drug degradation, caused by the relatively high processing temperatures, was avoided because of the short residence time of the drug in the barrel (2–3 min).

IMPORTANT APPLICATIONS

Sustained-Release Dosage Forms Made Using Melt-Congealing Processes

Many prolonged- or sustained-release dosage forms are made using melt-congealing processes. The dosage forms can be melt-congealed matrix granules in the form of capsules or compressed into tablets or melt-congealed coatings on drug-loaded substrates (particles or pellets in capsules). Wax matrices are often prepared by melt-granulation or melt-extrusion processes, whereas microspheres or microparticles are usually produced by spray-congealing processes, and coated particles or pellets can be made by hot melt-coating processes.

The formation of drug containing wax-coated microspheres can be considered a coating process, although it is more correct to describe it as an encapsulation process involving a phase-inversion technique. Giannola et al. (16) demonstrated this technique by producing carnauba wax microspheres loaded with valproic acid (VA). These microspheres were between 200 and 425 μm in diameter, with an average drug content of 26% w/w. The process used to manufacture this product consisted of melting carnauba wax in an oil bath at 110°C and then adding a sample of the VA. To this homogeneous melt was added an acidic aqueous solution (pH 4.5), which minimized the solubility of the VA, combined with glycerine, which increased the melting point. A small amount of surfactant (Tween or Spans[®]) was added, and then the mixture was stirred at a predetermined rate. On dispersion in the aqueous medium, the molten mass formed spherical particles. The mixture was then quenched by the addition of iced water, with the result that the carnauba wax solidified and enveloped the drug.

Miyagawa and coworkers (25) used a twin-screw extruder to prepare wax matrix granules (WMG)

consisting of diclofenac sodium (DS) as a model drug; carnauba wax as the matrix material; and hydroxypropylcellulose (HPC-SL), methacrylic acid and copolymer L (Eudragit L-100), and sodium chloride as rate-controlling agents. The dissolution behavior of DS from WMG was strongly influenced by granule formulation. The release rate can be manipulated by the addition of other rate-controlling agents.

Emori et al. (26) formulated wax matrix tablets for prolonged drug release using a melt-congealing process. They studied the addition of acrylic acid polymer on the release of drug from a wax matrix consisting of carnauba wax and stearyl alcohol in a 1:1 ratio.

Perez and colleagues (24) prepared sustained-release phenylpropanolamine HCl tablets and investigated the effects of varying wax levels and methods of matrix formulation on drug release. Two methods were used for the preparation of a drug-wax system: physical mixtures and solid dispersions. In the first method, the drug, wax, and diluent were blended in a Turbula mixer by geometric dilution for a total of 20 min. Then the mixture was compressed into tablets. For the solid-dispersion method, the wax was melted in a water bath at a temperature of 80–85°C. The drug was incorporated into the melted wax using constant stirring over a 5-min period, and then the mixture was allowed to cool until it solidified. The solidified mass was granulated using a Stokes oscillating granulator equipped with a no. 12 screen. Blending of milled material (wax and active ingredient) and diluent was done in the Turbula mixer for 20 min. The tablets that were prepared as a physical mixture gave higher drug release than did tablets prepared by the solid-dispersion process.

The formation of a barrier coat on drug-laden substrates, to protect the drug from gastric fluid or to provide sustained release of the drug, can be achieved by the hot-melt fluid-bed coating process. Processing conditions must be chosen to prevent solidification of the coating material in the feed lines and to obtain smooth, uniform coats without excessive spray-drying and agglomeration. Kennedy and Niebergal (19) coated chlorpheniramine maleate (CPM)-loaded nonpareils with hydrophobic coating agents such as beeswax, paraffin, etc. in a hot-melt fluid-bed coating process. They demonstrated the ability to extend the release profile of a highly water-soluble drug, CPM.

Solid Dispersions for Improving the Solubility of Poorly Water-Soluble Drugs

As previously noted, the use of solid dispersions to improve the solubility of poorly water-soluble drugs dates

back to 1961 (1). Pharmaceutical composition with good dissolution and bioavailability can be formulated from solid dispersions of pharmaceutically active ingredients. Solid dispersions also can be used in controlled-release formulations.

The principle of improving the solubility of poorly water-soluble drugs using solid dispersions has already been presented. One common method of preparing solid dispersions is melt-congealing. The carriers used to make solid dispersions of poorly water-soluble drugs have also been addressed.

Dispersions of drugs in matrices can be formed either by dissolution of the drug in a molten solid and subsequent solidification or by the mechanical dispersion of the drug in a molten liquid followed by solidification. If the drug is poorly water soluble, then the matrix material should be either highly water soluble or highly water permeable. The equipment used for the preparation of drug dispersions is quite varied and includes spray congealers, granulators, and melt extruders.

Nifedipine is a poorly water-soluble drug, and much research has been conducted to improve its solubility. Suzuki and Sunada (15a) prepared solid dispersions of nifedipine in a combined carrier of nicotinamide and hydroxypropyl methylcellulose (HPMC). The nicotinamide was melted at 140°C, and then the drug and HPMC were added into the melt and dissolved. The melt mixtures were cooled and solidified to form the nifedipine solid dispersions. The solubility of the drug in the solid dispersion was enhanced. The drug dissolution of this ternary dispersion system was influenced by the viscosity and weight fraction of HPMC, the solubility and weight fraction of the drug, and the humidity during storage.

Suzuki and Sunada (15b) also prepared solid dispersions of nifedipine with other combined carriers using a fusion (melt) method. The combined carriers were nicotinamide and four different water-soluble polymers: hydroxypropyl methylcellulose (HPMC), polyvinylpyrrolidone (PVP), partially hydrolyzed polyvinyl alcohol (PVA), and pullulan. HPMC, PVP, and PVA dissolved in the melt of nicotinamide and were effective in the amorphous formation of nifedipine in solid dispersions. In dissolution studies, the drug concentration for these dispersions increased to more than twice the intrinsic drug solubility.

Hirasawa and coworkers (12) prepared a naproxen solid dispersion by melting, followed by rapid cooling with liquid nitrogen using lactose as a carrier. The dissolution studies of naproxen indicated that the dissolution rate was markedly increased in solid dispersions compared with physical mixtures and pure drugs.

Doshi et al. (32) prepared solid dispersions of carbamazepine in polyethylene glycols (PEG), PEG 4000

and PEG 6000, by both the melt and solvent methods. A comparison of dissolution profiles of the solid dispersions indicated dramatic increases in the rate and extent of carbamazepine dissolution from the solid dispersions. The melt (congealing) method provided a significantly higher rate and extent of dissolution of carbamazepine than did the solvent method. In addition, the rate and extent of dissolution of carbamazepine were significantly greater when the solid dispersion was cooled (slowly) at room temperature compared with faster cooling with ice.

Van den Mooter et al. (33) prepared solid dispersions of tamazepam in PEG 6000 and polyvinylpyrrolidone K30 (PVP K30) by the fusion (melting) and cooling process. In contrast to the very slow dissolution rate of pure tamazepam, the dispersion of the drug in the polymers enhanced the dissolution rate considerably. This can be attributed to improved wettability and dispersibility and a decrease of the crystalline fraction of the drug.

Taste-Masking and Prevention of Environment Degradation

Yajima et al. (30) applied the spray-congealing technique to mask the bitter taste of clarithromycin, a macrolide antibiotic. An optimum wax matrix formulation was developed consisting of 30% clarithromycin (CAM), 60% glyceryl monostearate (GM), and 10% aminoalkyl methacrylate copolymer E (AMCE). The CAM wax matrix was made by a spray-congealing agglomeration process. AMCE was dissolved in melted GM at 12°C. CAM was added to the melt and homogeneously suspended. Subsequently, the suspension was transferred to a spray-dryer and atomized under various atomizer wheel speeds and liquid feed rates. It was found that a small spherical matrix with a smooth surface could be obtained with a high atomizer wheel speed and optimum liquid feed rate. This matrix also possessed excellent properties for taste-masking with small initial amounts of release and subsequent high rates of release.

The masking of unpleasant taste and the prevention of environmental degradation of the drug can also be achieved by applying a barrier coating in a melt-congealing process.

THE STABILITY AND STRUCTURE OF THE CONGEALED MATERIAL

Analytical Techniques

Differential scanning calorimetry (DSC), x-ray diffraction (XRD), and infrared spectroscopy are the common

techniques used in the characterization of the structure of the congealed solid. Thermal analytic methods, such as DSC and differential microcalorimetric analysis (DMA), are routinely used to determine the effect of solutes, solvents, and other additives on the thermomechanical properties of polymers such as glass transition temperature (T_g) and melting point. The x-ray diffraction method is used to detect the crystalline structure of solids. The infrared technique is powerful in detecting interactions, such as complexation, reaction, and hydrogen bonding, in both the solid and solution states.

Case Studies

Numerous studies have been reported in the literature that investigate the micro- and macrostructure of the congealed solid and its affect on the dissolution of the active ingredient. The structure of the solid phase formed on congealing is affected by the process by which the material is congealed, the formulation, and the conditions at which the solid product is stored.

Zhang et al. (14) produced matrix tablets containing chlorpheniramine maleate (CPM) dispersed in mixtures of polyethylene oxide (PEO) and polyethylene glycol (PEG) using melt-extrusion. Physical characterization of the samples was performed using differential scanning calorimetry (DSC), wide-angle x-ray diffraction (WAXD), infrared spectroscopy, and gel permeation chromatography. Results showed that the PEO and PEG consisted of ordered crystal regions interdispersed in random amorphous regions. WAXD verified that crystals of CPM and PEO existed in the matrix tablets. The effect of PEG was to lower the processing temperature and also the required torque necessary to extrude the melt through the die. This, in turn, had the effect of reducing damage to the polymer (and drug) during tablet formation. Polymer damage was primarily attributed to the intense shear force occurring during extrusion. This caused bond breakage and a reduction in molecular weight. The introduction of PEG caused a significant reduction in the melt viscosity and thus allowed a reduction in the processing temperature. An increase in the ratio of PEG to PEO also caused an increase in the rate of drug release during in vitro dissolution tests.

Emas and Nyquist (17) investigated the aging and stabilization of spray-congealed solid dispersions of carnauba wax. Isothermal microcalorimetry (IM) was used to measure the behavior of samples of freshly congealed wax and samples stored for 2 days at elevated temperatures of 40, 50, and 60°C, respectively. Results for the freshly obtained sample and the annealed samples are illustrated in Fig. 6, where the rate of change of heat content (dq/dt) is plotted as a function of testing time.

Fig. 6 Results of microcalorimetric measurements of spray-congealed carnauba wax. Untreated sample and samples annealed at different temperatures and stored for 5 days at ambient conditions; all measurements taken at 45°C. (From Ref. 17.)

Exothermic reactions are represented by positive deviations, whereas endothermic reactions are represented by negative deviations. From this figure, it can be clearly seen that the effect of annealing the samples at different temperatures is to reduce the magnitude of the exothermic reaction. The absolute values of the deviations depend on the temperature at which the experiments are run. However, the trend of reduced exotherms with increasing annealing temperature is followed for all temperatures. A series of experiments was also performed to evaluate the effect of long-term storage on the rate of change of heat content with time. Again, the results depend on the testing temperature, but the trends are similar. Fig. 7 illustrates the results for a wax sample annealed at 50°C for 2 days and then sealed and stored at room temperature for up to 12 months. From this figure, it can be seen that the initial

Fig. 7 Results of microcalorimetric measurements of spray-congealed carnauba wax. Samples annealed at 50°C for 2 days and stored for various times at ambient conditions all measurements taken at 45°C. (From Ref. 17.)

exothermic reaction is reduced in magnitude with increased storage temperature and that a stable condition (similar to that obtained for the raw wax) is approached asymptotically with time. From this work, it can be seen that spray-congealed carnauba wax initially exists in an unstable form that slowly changes to a stable form on storage (aging). This aging process can be accelerated by annealing the samples at an elevated temperature (40–60°C) for several days before storage. However, the rate of aging is a complex function of the annealing history because the wax appears to have different stable states at different temperatures.

Eldem et al. (34) investigated the polymorphic behavior of congealed micropellets of two different drugs (estradiol cypionate and medroxyprogesterone acetate) in two lipids, GTS-33 (glycerol tristearate) and Compritol 888 (glycerol behenate). Micropellets were formed from the drug and congealable matrix (tristearate-behenate), and then separate samples were taken, sealed, and stored for 6 months at temperatures of –18, 4, 25, and 37°C, respectively. DSC was used to investigate the stability of the samples after the storage period, and scanning electron microscopy (SEM) was used to measure the surface morphology of the microspheres. It was concluded that all the samples initially possessed an unstable polymorphic structure with a smooth surface morphology corresponding to the α -form, which is the result of rapid crystallization from the melt. According to Garti and Sato (35), the α -form possesses a very small crystal size accounting for the smooth surface morphology. The rate of attainment of the more stable β -form is dependent on the storage temperature. The presence of additives, such as lecithin, can also significantly affect the rate of change of crystalline structure. Higher storage temperatures increase the rate of polymorphic transformation, whereas the addition of lecithin acts as a stabilizer, slowing this transition.

McGinity et al. (36) investigated how the cooling process influenced the properties of solid dispersions prepared by congealing mixtures of drug and wax matrix. The system that was studied was tolbutamide in urea and in PEG (6000). Powder x-ray diffraction was used to determine the extent of crystallinity of these solid dispersions. For the tolbutamide–urea system, rapid cooling of the melt gave rise to distinct crystalline forms of the drug and wax. However, slow cooling of the melt in an oil bath at ambient conditions over a period of several hours yielded a solid that exhibited a complete absence of crystallinity. This amorphous solid did yield a crystalline structure after 5 months of storage, but the crystals were those of urea only. This is in contrast to simple physical mixtures of the two solids that clearly

showed crystalline mixtures of both tolbutamide and urea. In contrast to the tolbutamide–urea system, the tolbutamide–PEG system showed similar degrees of crystallinity for both the rapid-cooled and slow-cooled systems. Dissolution profiles for this system were compared for the rapid-cooled, slow-cooled, and physical mixture samples. The profiles for all three samples were very similar; however, the extent of release from the rapid-cooled sample was approximately 10% higher than that of the other two samples at any given time during the dissolution process.

Coben and Lordi (37) investigated the hardening of a variety of suppositories using a modified Krowczynski (38, 39) apparatus. The suppository bases were commercially available materials that consisted of a mixture of natural and synthetic waxes and fats. Samples were prepared from the different base materials by coagulating melted materials in 50-cavity brass molds. The samples were allowed to set at different storage temperatures (–5, 4, and 22°C), and this resulted in molding times of approximately 5, 15, and 30 min, respectively. After molding, samples from each batch were stored at three different temperatures of 4, 20, and 30°C, respectively. Both DSC and XRD were used to evaluate crystalline and polymorphic changes in the suppository base material. The results clearly indicated that the age-hardening phenomenon was solely attributable to a shift from an amorphous to crystalline structure and that polymorphic changes did not occur. Results also showed that the times required to resoften the samples at a given condition were dependent on the storage temperature but did not depend on the rate of solidification during the molding process.

From the case studies presented here, it is clear that the structural changes in the congealed material vary considerably and that it is difficult to identify and generalize these trends for a family of excipients. Nevertheless, it is fair to say that aging effects are common to many congealed materials and that carefully planned experimental studies must be conducted to evaluate the different phenomena causing these changes.

ADVANTAGES AND DISADVANTAGES

The advantages of using melt-congealing processes are numerous. Generally, no solvent is required in the formulation and manufacturing processes, and the subsequent environmental requirement of solvent capture and recycle is eliminated. Processing times are often much shorter because solvent evaporation is not required. For example, in coating processes, the time to congeal a molten

liquid is much shorter than that required to evaporate a solvent. In addition, undesirable drug–solvent interactions are also eliminated. For example, drugs that are highly water labile can be processed using melt processes.

There are also disadvantages to using melt-congealing processes. The drug must be stable at the temperature required to melt the carrier. For many drugs, the temperature at which degradation takes place is low and may preclude the use of all suitable matrix materials. Processing using hot-melt flows requires careful engineering to avoid feed-line solidification and unwanted agglomeration. Many of the matrix materials used to form dispersions and coatings undergo aging during storage, and this can affect the stability of the drug and/or the release rate of the drug.

SUMMARY

There are many applications of melt-congealing techniques in controlled-release dosage forms, improving the solubility of poorly water-soluble drugs and taste-masking of bitter drugs. Although the incorporation of an active ingredient into solid dispersions is a good way to enhance the solubility of poorly water-soluble drugs, the stability and aging problems associated with the congealed solids still need extensive additional study.

CONTRACT MANUFACTURING

Duncan E. McVean

Consultant, Solon, Ohio, U.S.A.

INTRODUCTION

Changes in Technology

Exciting changes are occurring in the pharmaceutical industry. Due to new advances in technology the industry is expanding more rapidly than ever before. For example, scientists are now using computers to manipulate molecules instead of having to go into the laboratory. Using computer simulations, they can design molecules that fit into cellular receptor sites. These “designer” molecules then produce desired therapeutic effects. Other scientists are using genetic manipulation to expand the realm of therapeutics. By inserting specific genetic material into mammalian, insect, and bacterial cells, cultures of manipulated cells produce hormones and other naturally occurring, physiologically active substances that are useful in the treatment of many disease states. Genes are also being inserted into embryos of farm animals; in adulthood, these animals are able to secrete therapeutically active substances in their milk and will become very low cost producers of substances that had either been in limited supply or had been very expensive to produce by other methods.

Changes in Core Business of Companies

To accommodate this changing technology, the core business of many companies will require capabilities that they do not presently have. In addition, many businesses have realized that being “prime” from Basic Research to Marketing and Distribution is no longer economically practical. Some companies have even decided to dedicate their facilities solely to research. Others have decided to exploit a particular niche. Companies that continue to be prime are becoming fewer and fewer.

Outsourcing Defined

Previously, the paradigm of the pharmaceutical industry required companies to be vertically integrated, i.e., the company itself performed all the operations required of its business. Now investors are demanding continued

high financial performance. In an effort to reduce time-to-market, companies are more and more focusing their attention on their core competencies. As a result “outsourcing” has become a significant way of doing business. Outsourcing is the system of using a nonrelated company to produce materials or perform tasks for another on a contractual basis.

The New Paradigm of Doing Business

Outsourcing has resulted in the development of a new paradigm for doing business. This paradigm offers companies new opportunities for improving their bottom lines through the conversion of fixed costs to variable costs. They accomplish this by reducing or eliminating in-house production capabilities and replacing them with contract manufacturers. As a result, contract manufacturers that perform custom synthesis and produce intermediates, active pharmaceutical ingredients, and dosage forms are becoming increasingly important to the conduct of today’s business.

Change from Vertical to Horizontal Integration

As a result, companies are becoming more horizontally rather than vertically integrated. Rather than expanding or upgrading their own facilities to accommodate new technology, companies that outsource have realized that a new product can be brought to market with greater speed than if they had performed all of the tasks internally. As an additional benefit they have positively affected their profitability through reduction of their need for investment in bricks and mortar.

The Virtual Company

The outsourcing industry has also spawned a new type of company, the “virtual” company. The concept of a virtual company is based entirely on the use of contract manufacturers, laboratories, and other providers of services to take a product from concept to market. Such a company is truly horizontally integrated. Furthermore, it has the advantage of requiring only a few managers to

coordinate the activities of various contractors as it conducts its business.

Supply Chain Management

A new breed of managers is developing within existing organizations that have decided to outsource. Their job is to effectively link the services of several contract manufacturers to forge a supply chain that performs all of the steps between R&D and Sales/Marketing. The resulting supply chain requires little or no investment of capital and achieves the same results previously obtained through vertical integration.

CONTRACT MANUFACTURING DEFINED

Origin

Contract manufacturing first began when one company asked another to produce for them a product that they chose not to produce themselves. Contract manufacturers can be found throughout all industries. Instead of producing their own “brand name” products, they provide production and other services to all comers. And, because their facilities are designed to be flexible, the same facility can make products for many customers.

Types

Contract manufacturers can be classified into two types, i.e., those who “supply” and those who “toll”. Regardless of type, all contract manufacturers have the common denominator of providing one or more services for a fee.

Suppliers and Tollers

A contract manufacturer is one who supplies manufacturers materials for inventory. This supplier sells products from its inventory to one or more companies for their use or disposition. This type of contractor is sometimes known as an “original equipment manufacturer.” On the other hand, a “toll manufacturer,” or “toller,” is a manufacturer who contracts to

- receive a raw material from another company.
- convert that material into another form, and
- return the converted material to the contracting company for its use or further disposition.

The basic difference between these two types of contractors is that one manufactures for its own inventory,

while the other manufactures according to a custom order. To cloud this picture, either type of contractor may provide both functions.

Types of Tollers

Sellers of Excess Capacity

Companies that engage in toll manufacturing can be further classified into three fundamental types. First are companies that have more capacity than they need to produce an established product line. Rather than let that excess capacity stand idle, the companies use it for toll manufacturing to reduce the burden of salaries and overhead attached to the excess capacity while concurrently producing additional income. Pricing for services from these manufacturers are usually quite favorable, since their product line is absorbing their fixed costs. Only variable costs associated with the excess capacity are incurred.

Providers of Niche Services

The second type of toller is comprised of companies that, rather than marketing an established product line of their own, have concentrated on a niche service. Their facilities, equipment, and personnel have been designed only to accommodate specialized operations such as lyophilization and production of parenterals. Their success is dependent upon being able to lease their facilities and technology for the production of products for one or more customers. Their focus is on making products without having to worry about heavy R&D and marketing. A positive advantage for the use of this type of company is that they are less likely to compete with their customers.

Academic Institutions

The last type is comprised of academic institutions that provide assistance with custom synthesis, dosage form development, pilot-scale production, and production of clinical supplies in order to obtain additional income to support their academic programs. They have no interest in, nor are they equipped for, commercial production. Companies seeking outsourcing should be aware that students and faculty could form part or all of the staff of their operations; this may be a disadvantage when considering using this type of contract manufacturer.

HOW TO DETERMINE WHEN A CONTRACT MANUFACTURER IS NEEDED

The need for the services of a contract manufacturer can occur at any time during the developmental phases and/or

commercial manufacture of a product's life cycle. Such situations occur when

- Specialized manufacturing capabilities are required that are not available in-house.
- Assistance is needed with product and/or process development.
- The need to establish the market potential of a new product is required before investing in specialized capabilities.
- Difficulty is encountered in breaking into the manufacturing schedule in a timely manner to produce small research, clinical, or commercial batches.
- Production requirements cannot be accommodated when sales exceed capacity.
- Capacity is needed for the production of new, growing products, yet a place for the manufacture of products that are at the end of their life cycle still needs to be provided.

Advantages of Working with a Contractor

Developing companies especially can gain many advantages from working with a contract manufacturer. First, they gain access to production facilities without having to invest any of their own limited capital. Second, they instantly add a breadth and depth of expertise in pharmaceutical manufacturing to their operations that would have taken years to develop. Third, they gain the use of the contractor's operating personnel. Depending on the special niche of the contractor, the contractor's personnel will be experienced in one or more pharmaceutical specialties. These include custom synthesis; production of intermediates and active pharmaceutical ingredients; formulation development; lyophilization cycle development; aseptic processing; sterilization process development; regulatory assistance; sourcing of excipients; analytical methods development; validation of processes and methods; package development; and storage and testing of stability samples.

Disadvantages of Working with a Contractor

But, a company seeking to outsource must also be familiar with negative aspects associated with working with a contract manufacturer. A major disadvantage to developing companies is that the client is entrusting to another entity its valuable intellectual property that before was a closely guarded secret. Clients also must consider that they are but one of the contractor's many clients. As a result, due to competition for the contractor's resources, projects may not move forward as fast as a client may desire.

Finally, clients incur the costs of at least a portion of the salaries and overhead of the contract manufacturer.

HOW TO SELECT A CONTRACT MANUFACTURER

Involvement of Purchasing Department

After evaluating the pros and cons of using a contract manufacturer, how is one selected? The selection process is very important to avoid disappointment later. Some companies require that all searches be conducted under the auspices of their purchasing department. In such cases, the purchasing department should be requested to initiate a search. Regardless, whether such a policy exists or not, close collaboration with the purchasing department is advisable during all of the following steps in the selection process.

List of Requirements

Begin any search by developing a list of requirements that a potential contractor must satisfy in order to be considered. Provide this list of requirements to the purchasing department. The most fortunate situation that can occur in the selection process is finding that the Purchasing Department is already employing a contract manufacturer with the capabilities to perform the required task.

Referrals from Colleagues

After developing the list of requirements, begin your search by seeking referrals from colleagues in the industry. There is nothing better than obtaining a recommendation about a particular contract manufacturer from someone that has successfully used its services. You can question your colleagues about any idiosyncrasies they experienced with the operations of recommended contractors. These queries can also explore the degree of satisfaction experienced regarding the manufacturer's compliance with mutually agreed upon requirements. Finally, an opinion can be obtained regarding the qualifications of the contractor's personnel assigned to projects. Be sure to solicit information as to how those personnel interrelate with customers.

Use of Information Sources

Contract manufacturers can be identified by their specialty through the use of commercial information sources (1, 2) and by review of advertisements in trade journals (3).

Commercial information sources solicit profiles of contract manufacturers for their databases. Contract manufacturers usually advertise their services in journals having the widest circulation within an industry. Many of these journals print annual buyer's, guides in which their advertisers are grouped according to the services they provide. The Internet is also a useful tool to identify contract manufacturers. Several sites are listed in the Reference section (4).

Trade Shows

Trade shows provide excellent opportunities to seek out and meet contract manufacturers. Contract manufacturers operate exhibits where literature on their companies can be obtained for later evaluation. Talking with the exhibitor's personnel provides an opportunity to conduct preliminary discussions with contractors about the services they offer. You can determine on the spot whether or not a particular contractor will be suitable for your project.

Trade shows often feature speakers on topics concerned with contract manufacturing. Attend such programs to familiarize yourself with the intricacies of contract manufacturing. You will find that your notes and handouts from the speakers will contain the latest information on this subject.

The Interview Process

Once you have identified a list of potential contractors, begin communicating with them by telephone. Table 1 provides suggested questions that can be used during interviews. Begin the interview by explaining that you are conducting a search for a contractor, and that they have been preliminarily identified as having the capability to meet the requirements of your upcoming project. Then, request them to send the most current information about themselves and their capabilities. To assure due diligence in your search, include at the conclusion of each interview a request for them to give you the names of any other contractors that they feel might be able to meet your requirements. Additional contractors identified in this manner should be contacted and interviewed, especially those who were suggested by more than one other company.

“Very Good” vs. “Excellent” Contractors

A few contractors have reached the point of being identified as being “very good” at what they do. Once this status has been reached, their business usually increases and downtime decreases. However, the nature of a

contractor's business poses problems with advancing further in status, i.e., involvement with many customers, frequent changeovers of equipment, and production of many batches of a multiplicity of products. Advancing to the status of being “excellent” presents a unique challenge, because an “excellent” contractor is one that manages schedules so that time is allocated for concentration upon the nuances of any one process, smoothing out the rough edges, and achieving perfection. Your search should strive to identify the “excellent” contractors.

Confidentiality Agreement

After a list of “finalists” has been assembled, execute a confidentiality agreement with them. Only after such an agreement has been executed between your company and the contractor should the project be discussed in greater detail. Once provided with detailed knowledge of the project, the potential client and contractor can then determine whether a match exists between the requirements of the project and the contractor's capabilities.

Agenda for First Meeting with Selected Contractor

The final step in the process is to select one of the finalists and to request a meeting to discuss the project in greater detail. A sample agenda for such a meeting is contained in Table 2. Any information that the contractor will require in preparation for this meeting should be provided before the meeting. Additional meetings will probably be required before work can be initiated.

Statement of Work

Following the initial meeting, the contractor will evaluate the information provided. A prudent contractor will then provide an itemized proposal describing the work that would be necessary to be completed before the client's product can be introduced into the production schedule. The contractor and client should meet as often as necessary until both sides can agree upon a statement of work to be provided by the contractor that will accomplish the goals of the client.

DEVELOPING A CONTRACT

Basic Elements and Governing Procedures

The parties involved in developing a manufacturing contract generally understand that the contract will include

Table 1 Questions to be used when defining requirements sought in a contract manufacturer

-
1. What services are to be provided by the contractor?
 - Formulation development?
 - Process development?
 - Experience with and the capability to produce a particular dosage form?
 - What manufacturing capacity is required?
 - Testing laboratories?
 - Document preparation and editing?
 - Capability for distribution?
 - Regulatory assistance?
 - Aseptic processing?
 - Lyophilization?
 - Terminal sterilization?
 - Validation?
 - Quality assurance?
 - Inspection?
 - Labeling?
 - Packaging?
 - Stability studies?
 2. Does the contractor have the capability, facilities, and capacity to manufacture both clinical supplies and commercial products? (Otherwise, approval of another manufacturer will have to be obtained before the product can go to market.)
 3. How flexible is the contractor with regard to formulation, manufacturing, quality assurance, labeling, and packaging?
 4. Are “turn key” services such as development, control, and distribution available?
 5. Do the manufacturing facilities conform to current good manufacturing practices ?
 6. Does the contractor allow inspection of the facilities?
 7. Does the contractor allow the client to audit the manufacture of each batch of a client’s product?
 8. Does the contractor have an established process to monitor and improve quality?
 9. Does the contractor supply a list of minimum requirements that are expected of its clients?
 10. Does the contractor provide a product information questionnaire to be completed before a project begins?
 11. Does the contractor insist that both parties review and approve master batch records before their use?
 12. Does the contractor require that a representative of the client be on site during the manufacture of the client’s product, or require that the client have a knowledgeable person on-call at all times to provide immediate response to questions that arise during manufacturing?
 13. Does the contractor offer analytical support? Is this support adequate?
 14. Does the contractor provide a protocol of analysis or a certificate of compliance for each lot of product at the time of shipment as well as copies of completed batch records?
 15. What is the contractor’s policy regarding loss of customer supplied materials when the loss is due to its own negligence, or its failure to perform according to mutually agreed upon standards or obligations?
 16. Does the contractor encourage innovation rather than maintaining the status quo? What examples of new practices, procedures, etc., can it describe?
 17. Will the contractor provide a letter of access to its facilities master file?
 18. What is the contractor’s relationship with regulatory authorities?
 19. What is the contractor’s posture during regulatory inspections?
 20. Does the contractor offer confidentiality agreements?
 21. Is the contractor willing and able to enter into long-term supply agreements?
 22. Is the contractor selling the excess capacity of its parent company?
 23. Can the contractor comply with the established timetable?
 24. How responsive is the contractor’s customer service department?

(Continued)

Table 1 Questions to be used when defining requirements sought in a contract manufacturer (*Continued*)

25.	Is the contractor an equal opportunity employer?
26.	Has the contractor had experience in supplying materials for government contracts?
27.	Does the contractor produce any products for its clients that are shipped or sold internationally?

The answers to the above interrogatories will help in the selection of a contractor who can provide the services desired.

a definition of what is to be manufactured, what the cost will be, and when the product is to be delivered. Beyond these basic elements, the client and contractor are well advised to jointly develop written procedures that detail how the client and contract manufacturer are to interact and thus ensure that appropriate actions are taking place. These procedures can either be included in the contract or take the form of mutually agreed upon internal operating procedures. Further, the contract must specify how the client reviews and approves all processes specific to the manufacture of the drug product. The client is then obligated to generate operating procedures that describe the mechanisms that will be used for review and control and provide these to the contractor. The client has the added responsibility of having written procedures in place to ensure that the contractor complies with all previously agreed upon requirements. A copy of these procedures must be given to the contractor, providing awareness of the client’s standards.

Conformance to Precepts

Basically, the contract must ensure that the client can expect the highest level of professionalism from the contractor, that a high quality product is being provided, and that the product is being produced according to cGMP at a fair price. The contract manufacturer is only selling its

services and its quality process; therefore, conformance to these precepts is the reason for being selected as your contract manufacturer. A list of the clauses usually incorporated into a standard supply agreement for Goods and Services is included in the Appendix to this article.

COSTS

Contractor’s Fee for Service

What does it cost to use a contract manufacturer? Although contract manufacturing may seem expensive, the use of a contractor does enable a client to dedicate its resources to more productive activities than maintaining a variety of production facilities. In return for providing the client with other opportunities for its resources, the contractor expects to receive a fee commensurate with its investment in capital equipment, wages and benefits for personnel, materials to be supplied, overhead, batch size, and a reasonable profit.

Fee Based on Expected Business

However, there is no set fee that can be universally applied to a contractor’s services. Remember, in most cases a contractor, unlike a regular manufacturer, has no product line. Whether or not it has business is entirely at the whim of its customers. The quantity of business available to the contractor is governed by how well a client’s products are doing in the clinic or in the marketplace. The contractor can make a guess as to how much business it will do each year, but the uncertainty is great. Therefore, a contractor usually bases his fees on the costs associated with each batch to be produced, rather than the projected total output of its production each year. To gain discounts, clients must be prepared to offer reasonable guaranteed production requirements.

Fee Related to Size of Batch

The size of the batch to be produced is a very important aspect to be considered when evaluating costs. Regardless

Table 2 A Sample agenda for an initial meeting with a contractor

I.	Welcome and introductions
II.	Tour of contractor’s facilities
III.	Detailed description of project
IV.	Question and answer period with contractor’s staff
V.	Client’s requirements and expectations
VI.	Contractor’s requirements and expectations
VII.	Agreement to proceed with or discontinue further discussions
VIII.	Development of timetable and identification of milestones, if appropriate
IX.	Business issues
X.	Adjournment

of the batch size, certain minimum charges for setup must be recovered. Obviously, the larger the batch, the more units are available over which to spread these charges, and unit costs diminish accordingly. Conversely, for the same reason, the smaller the batch size, the greater is the unit cost.

In-House vs. Using Contractor

When evaluating the appropriateness of a contractor's fee, a client must know its costs for doing the project in-house. Then it must consider whether the expense of adding the contractor's overhead and profit to the cost of goods is more than the in-house costs. Finally, a client must justify the cost of any delays in reaching the market as being more economical than the contractor's fee.

WORKING WITH A CONTRACT MANUFACTURER

Timetable

As a first step before beginning work with a contractor, both the client and the contractor must agree on a mutually acceptable timetable for completion of the project. This timetable should include decision points where reports and/or review meetings are required. Then, a principal contact at the contractor's site and one at the client's site need to be identified so as to assure that a uniform flow of communications can occur between the companies. The person assigned to be the client's principal contact will be responsible for monitoring the contractor's compliance with the timetable. Each party to the timetable must be agreeable to making revisions in the timetable should legitimate situations require.

Contractor's Input

From a contract manufacturer's viewpoint, it often appears that the client considers the contract manufacturer only as a provider of services with no expectation of providing input into the process of bringing the drug product to market. For a successful relationship this concept must be reexamined. Actually, the mutual best interest of both is best served by each acting as a partner of the other, freely sharing information that assures mutual success.

Communications

A contract manufacturer brings more than just a manufacturing facility to the partnership. The contractor is not just another pair of hands. The contract manufacturer

and its client must be able to communicate with one another as equals and with respect for each other's contributions.

Key to Successful Relationship

The client is well advised to listen to advice provided by the contractor and respect any concerns. After all, the contractor, while being careful to protect confidences, can call upon years of experience gained from working with other clients to provide insight into problems, regulatory concerns, etc., which a client may be experiencing for the first time.

Master Production Batch Information

Open channels of communication assure continued cooperation and successful outcomes. Encourage your contractor to have timely discussions with you concerning any problems or concerns experienced with the manufacturing process or with regulatory matters. Likewise, share with the contractor your data and any other information concerning analytical results, results from focus groups, any product complaints, and conclusions from clinical studies. By working together, adjustments can be made to manufacturing processes that will assure that a quality product is being produced. When using a contractor, always remember the following: A successful relationship can only occur when both parties work together to win.

Before the contractor can begin manufacturing activities, master production batch information must be developed. This master information package normally includes specifications for raw materials, components, analytical methods, finished product specifications, packaging instructions, and any other information pertinent to the product. The client is obligated to review and approve the master production information before allowing the contractor to proceed. This approval indicates that the client is satisfied that the contractor will be producing a product that will meet specifications.

Client's Representatives

A representative of the client should be present in the contractor's facilities during the production of the product. If the client elects not to have a representative present, the client should provide the contractor with the name of an authorized person who can be contacted at any time, day and night, to resolve any issues with the production which might occur during processing.

DISADVANTAGES TO WORKING WITH A CONTRACT MANUFACTURER

Use of Commercial-Sized Equipment for Small Batches

Some contract manufacturers are equipped to produce only commercial-sized batches of product. Because of this, the same equipment is also used for the production of smaller research and development scale batches. This is a disadvantage when batches are small, particularly where expensive materials in short supply are to be produced, because a considerable amount of bulk formulated product may not be able to be converted into finished product. Some materials will always be hung up in processing equipment, regardless of size. The materials that are hung up are not available for further processing. The quantity of hung up materials is related to the size of the processing equipment being used, and is relatively constant for that equipment. Unfortunately, when losses are being calculated, the smaller the batch size that is being produced in equipment designed for larger batches, the greater is the percentage loss of product.

Buy-Back Arrangements for Specialized Equipment

Another consideration when working with a contract manufacturer is whether specialized or dedicated processing equipment will be required. If dedicated or special equipment is required, the contract manufacturer may feel justified to ask the client to supply this equipment with or without a later buy-back arrangement. In a buy-back arrangement, the contractor asks the client to initially assume the full risk of loss of the capital investment in the equipment should the product not become a viable commercial entity. However, as the product successfully completes each stage of the steps to marketability, the client's capital investment would be gradually returned. The end result is that the contract manufacturer has all of the equipment needed for the manufacture of commercial-sized batches of the client's product at the time it is finally commercialized.

Liability

Then there is the question of liability. If an adverse event occurs in a client's own operation, the client absorbs the financial loss as a cost of doing business. How much liability for loss of product or materials during the manufacturing process should a client then expect a contractor to assume? A contractor will argue that, even

though a separate entity, during the time the contractor is manufacturing the client's product, the contractor's facility is an extension of the client's shop floor. Therefore, should an adverse event occur during production of the client's product, the contractor will expect the client to absorb any financial losses as if the losses had occurred in the client's own operation. Whether or not a client agrees with this argument, the amount of liability to be assumed by each party must be agreed upon during contract negotiations.

REGULATORY ISSUES

Status of a Contract Manufacturer

From a regulatory standpoint, Regulatory agencies do not differentiate a contract manufacturer from any other manufacturer under their jurisdiction. A contract manufacturer must comply with the same federal, state, and local regulations as would any other manufacturer. In the United States, prior approval must be obtained from the U.S. Food and Drug Administration (FDA) before a contractor can be used as either the primary or alternative manufacturer for a registered pharmaceutical product. Even though a contractor is being used, the contracting company still retains primary responsibility for assuring that the contract manufacturer complies with all of the commitments that were included in the product's registration and with all aspects of current good manufacturing practices (cGMPs).

Inspections

Regulatory agencies inspect contract manufacturers on a regular basis to ensure that these manufacturers are in compliance with cGMPs. In the United States, all reports of inspections by regulatory agencies are available to anyone through freedom of information. Any company contemplating the use of a contract manufacturer should review the regulatory history of all companies under consideration as part of the selection process. Likewise, client companies, as part of their contractual relationship, should have a contractual requirement that the contractor notify them should there be an inspection involving their product, or should there be any adverse findings from any inspection which would affect the continued supply of their product by that manufacturer.

Pre-approval Inspections

Regulatory Agencies also conduct pre-approval inspections as part of the process of review of registration

documentation. Prior to a pre-approval inspection, the client and the contractor should review all documentation that will be reviewed during the inspection. Clients should also assure themselves that the contractor is, indeed, in compliance with cGMPs.

International Considerations

If the client is marketing the product internationally, the client should provide the contract manufacturer with copies of the regulatory requirements that might affect the client's product in all countries in which the product is being marketed. A contractor cannot be held responsible for compliance with regulations with which the contractor is unfamiliar.

Master Files

A contract manufacturer should be willing to provide its clients with authorization to permit the regulatory authorities to reference the facilities master file that the contractor maintains in the archives of the regulatory authority. Or, if a facilities master file is not an appropriate vehicle for a particular type of registration, the contractor should provide sufficient information about its processes and procedures to enable a client to satisfy the requirements for manufacturing information in its application for the registration of its product. Although it is convenient to be able to use contractor-supplied information in the preparation of an application for registration of a product, the client must always completely review that information to ensure that, from a regulatory viewpoint, control of the product has not been inadvertently transferred to the contractor.

Special Requirements of the Biotechnology Industry

The biotechnology industry is one of the biggest users of contract manufacturing. Contract manufacturers are used to produce bulk active pharmaceutical ingredients by cell culture and/or fermentation. Then, other contractors may be used to convert the bulk active pharmaceutical ingredients into finished dosage forms. The regulations governing the use of multiple companies for these production activities are continually being refined by the FDA.

Dedicated Equipment

In some situations, the regulatory agency will require that dedicated equipment be used in manufacturing activities.

Should this requirement be imposed, many contractors require the client to purchase this equipment. This becomes another initial expense that must be added to the total cost of using a contract manufacturer.

Common Regulatory Theme

Regardless if the product is a "traditional" pharmaceutical or is a product of biotechnology, one common regulatory theme is always present. That is, the company employing a contractor retains responsibility for the product being manufactured and for ensuring that the contractor remains in compliance with the terms of the license and with cGMPs.

History of Contractor's Relations with Regulatory Agencies

Finally, before working with any contract manufacturer, potential clients must be assured that the contractor has a satisfactory history of cooperation with regulatory authorities. This type of information can be obtained from a review of several establishment investigation reports (available through freedom of information in the United States) involving that contractor.

Cooperation with Regulatory Agencies

Should a contractor regularly take an adversarial stance when dealing with regulatory authorities, there is more at stake than just defending that contractor's position. That contractor is potentially placing the continued production of the client's products in jeopardy especially if the dispute involves processes or procedures related to those products. For that reason alone, a potential client should not select that particular contractor for their project.

MONITORING THE CONTRACTOR

Quality Assurance Initial Audits

Prior to establishing any relationship with a contractor, the quality assurance staff of a potential client must audit the contractor's facilities. During this audit, the contractor should be willing to provide a comprehensive tour of the facilities. Following the tour, the auditors need to review all of the contractor's standard operating procedures that may apply to their company's proposed project. In addition, the auditors need to review the quality improvement process being used by the contractor and the results of that process.

Any concerns that have been identified during the audit should be discussed with the contractor at that time.

Actions to be Taken Upon Receipt of Audit Report

Upon completion of the audit, the auditors should provide the contractor with a report citing any problems which they have identified with the contractor's operation that might interfere with the contractor being able to successfully work on their company's project. The contractor should respond in writing to the audit report and address how they will handle each observation. Based on the results of their audit and the responses of the contractor, the audit team can then make a recommendation to the responsible personnel within their organization as to the acceptability of the contractor.

Representatives in Contractor's Facilities

Once manufacturing begins, most clients elect to have a representative present. The contractor should be willing to permit that representative to observe the processes in their entirety. Before any visit, however, the client must instruct its representative to comply with all of the standard operating procedures of the contractor while on the contractor's premises. Further, the extent a representative can be involved in the production process needs to be negotiated between the client and the contractor prior to sending a representative to the contractor's site.

Periodic Audits by Quality Assurance Staff of Client

After a client has established a working relationship with a contractor, the quality assurance staff of the client should be allowed to audit the contractor's facilities and operations on a regular basis, but usually not more frequently than once a year. Again, any observations concerning the contractor's operations arising from these audits require a written response from the contractor. If the responses are not satisfactory to the audit team, then the upper management of both companies must be called upon to immediately resolve the differences. Should this be necessary, the management of both parties must ensure that any proposed resolution remains within the terms of the contractual agreement.

Quarterly Meetings

Finally, it is good practice to hold quarterly meetings between the decision makers of both the client and the

contractor. These meetings ensure that both companies are still aligned to achieve mutual goals. These meetings allow the contractor to participate in the client's decision-making process as performance for the previous quarter is reviewed and plans for the following quarter are presented. Topics for discussion should include the contractor's conformance to the client's expectations, regulatory issues concerning the client's product(s), the contractor's recent regulatory experiences, sales forecasts, and any other items appropriate to the occasion.

CONCLUSION

Through skillful management and control, contract manufacturers can be used to take a product from the "test tube miracle" stage through the stage of being a "production masterpiece." Virtual companies have learned to do these tasks well, and have successfully linked multiple contract manufacturers together to form the horizontally integrated company of the future.

Points to Follow When Working with a Contract Manufacturer

Working with a contract manufacturer is quite easy provided that the following points are followed:

- Finalize the decision to use a contract manufacturer early in the timetable of the project.
- Involve the contractor in decisions, e.g., formulation, components, regulatory, etc.
- Do not file specific requirements in regulatory documents without first assuring that the contractor agrees.
- The client and the contractor have mutually agreed upon the requirements of the project *before* beginning the project.
- The client has designated someone from their staff with whom the contractor can make contact *at any hour* to resolve difficulties.
- Remember the Golden Rule—Do unto the contractor, as you would have the contractor do unto you.

APPENDIX: ELEMENTS OF A CONTRACT

The following list of clauses are usually incorporated into supply agreements for goods and services. The author developed this list using his experience of over 15 years reviewing various supply agreements. Potential clients can

use this list to ensure the completeness of their agreements. Depending on the situation, additional elements may be appropriate while others may not. The aim in any contractual relationship is to achieve a win/win situation for both parties. This aim can only be accomplished through good faith and due process during the process of negotiation.

The Checklist

1. Payment terms
2. Forecasting process
3. Quality standards—Test methods
4. Pricing
5. Liabilities—Both parties
6. Specification(s) of item(s) or service(s) to be supplied
7. Transportation and limit of responsibility from the point of ownership
8. Right of audit and inspection
9. Term and renewals
10. Warranties
11. Prior approval over product or process changes
12. Confidentiality
13. Alternate supply in case of failure to supply
14. Limitations to subcontract
15. Acceptance
16. Third-party laboratory for resolution of testing disputes
17. Insurance
18. Supply over-forecast amounts
19. Firm purchase orders
20. Change of control
21. Assignment rights
22. Penalties for failure to perform
23. Stability responsibilities
24. Recall responsibilities
25. Survival
26. Exclusive/nonexclusive total requirements
27. Force majeure
28. Regulatory/state/federal law/cGMP compliance
29. Separability
30. Notices
31. Arbitration and dispute resolution
32. Governing law
33. Amendments
34. Notification of price changes
35. Accuracy
36. Complete agreement
37. Supplier certification
38. Adverse reaction reporting—Product complaints
39. Independent contractor
40. Allocation of capacity in event of shortage
41. Royalties
42. Supply and storage conditions
43. Capital costs and tooling
44. Yields—Over/under shipments quantity
45. Trademark rights
46. Patent rights
47. Rejections
48. Safety stock requirements and liability for obsolescence
49. Ownership of technology or proprietary information
50. Taxes
51. Human resources—Government, EEOC requirements
52. Definitions
53. Index
54. Customs and duties
55. Noncompete

COMPUTERS IN PHARMACEUTICAL TECHNOLOGY

Onkaram Basavapathruni

Pharmacia Corporation, Peapack, New Jersey, U.S.A.

INTRODUCTION

The computer has become a very common tool in all areas of science and technology, and there seems to be no end in sight for future applications. With the proliferation of the Internet and the developments in computer technology and manufacturing, the ratio of price-to-performance of computers continues to decrease. This has resulted in the development of a number of computer applications. The field of pharmaceutical technology has also benefited from the use of computers and will continue to benefit as the professionals in the field gain more familiarity with computers. This chapter will discuss some examples of existing computer applications, the fundamentals of computer technology, and issues to be addressed when applying computers in pharmaceutical technology and assessing their future applications.

COMPUTER APPLICATIONS

Computers have been successfully utilized in pharmaceutical technology to improve productivity, collaborate with other professionals, and to provide solutions for time-consuming manual tasks. For purposes of discussion, the various computer applications are classified as follows:

- Data and information management systems
- Interactive voice response systems
- Group collaboration tools
- Document management and publishing systems
- Internet-based applications and tools
- Problem-solving applications
- Communication aids
- Laboratory automation
- Process control
- Computer-based training

Some computer applications are so complex that it is difficult to classify them into any one of the categories. Nevertheless, any complex computer application can be broken down into smaller parts, and each part may then be described under one of the classifications.

Data and Information Management Systems

The first computers were primarily used for computational purposes. As hardware prices dropped and computer storage technology developed, it became cost-effective to use computers for storing vast amounts of data and information in a variety of formats (e.g., text, numbers, audio, image, and video). Along with the advances in computer hardware, software development also advanced rapidly and resulted in the development of database management packages, such as Oracle, Sybase, and Microsoft Access. By using these packages, a number of computer-based systems can be developed in-house in order to organize data and information and then to query the data in a number of ways. An alternative would be to acquire commercially available systems that use these popular database packages. In either case, the challenge with these systems is to determine what type of information has to be stored in the database and how it can be retrieved in a number of ways. These systems, when designed properly and implemented with active user participation, minimize the paperwork and improve the productivity of personnel involved. Data and information management systems are usually built by the in-house data processing department or acquired from a vendor to meet the needs of users in a given organization. More often than not, the same data management system can be implemented differently in different organizations. A number of systems will be described in general terms in order to give the reader an idea of the available data management programs.

Material inventory system

This system maintains a running inventory of raw materials used in pharmaceutical manufacturing. It will be updated at regular intervals when new materials arrive, as well as when materials are drawn out. This system is useful in tracking existing inventory, lot numbers, and quantities of raw materials needed for manufacturing a product, as well as other pertinent information. Some systems also accommodate the need to reserve a certain lot of raw material for use in manufacturing a particular batch of the product to be used for a stability or clinical study. A sample output from a material inventory system is shown in Fig. 1.

Inventory Report for GMP items

Description	Item #	Unit of measure	Lot #	Quantity
MICROCRYSTALLINE CELLULOSE NF/BP/DAB (AVICEL PH101/EMCOCEL)	Z00106	KGS	SP2359	50.00
MICROCRYSTALLINE CELLULOSE NF/BP/DAB (AVICEL PH102/EMCOCEL 90M)	Z00102	KGS	L00616	10.57
MICROCRYSTALLINE CELLULOSE NF/BP/DAB (AVICEL PH103)	Z00103	KGS	SP1029	9.70
MILLER FROCKS 5 SNAPS L CODE 1212	Z02204	CS	SP2059	1.00
MILLER FROCKS 5 SNAPS M CODE 1212	Z02205	CS	SP2060	1.00
MILLER FROCKS 5 SNAPS S CODE 1212	Z02206	CS	L00604	90.00

Fig. 1 Sample output from a material inventory system.

Formulation information system

This system can be used to store the information on raw materials that constitute a batch of a pharmaceutical bulk product. Typically, the lot numbers of the ingredient, the name of the ingredient, amount per dosage form, percent composition, weight of the batch, and the actual amount of each ingredient are stored in these systems. Other information, such as manufacturing summary, shipping history, and relevant storage information, is also stored. The system's greatest benefit is its different retrieval methods. For example, during product recalls, audits, or tracking an excipient problem, one might be interested in determining all the batches of products made using a particular lot of raw material. This system can also be used to archive the formulation information generated during formulation screening studies. Consequently, data collected in this fashion can be utilized for subsequent statistical analysis. This system can also act as a repository of information that might be helpful in serving as a knowledge base to develop new formulations.

Clinical supplies inventory system

In pharmaceutical research and development (R&D), a number of clinical trials are conducted to determine the therapeutic effectiveness of potential new drugs and novel dosage forms of well-established drugs. In order to provide the necessary clinical supplies in a timely manner and to plan for the manufacture of needed supplies, clinical supplies inventory systems are used.

Clinical supplies labeling

The clinical pharmacy is often called upon to supply complex labeling requirements for investigational drugs used in clinical studies. Depending on the number of patients and investigators, several hundreds or even thousands of labels with randomized patient and

investigator numbers are prepared. Well-designed computer programs eliminate the manual labor involved in hand-numbering each label. The computer also sorts the labels by investigators and treatment groups, and prints the labels accordingly. Examples of labels generated by a computer program are shown in Fig. 2.

Stability information systems

The pharmaceutical manufacturer conducts stability studies to develop stable dosage forms in a variety of packages and, in the process, generates vast amounts of data and information. Stability information systems are designed to organize these data and help retrieve the needed information to establish an expiration date for a product. The stability information is also submitted to the regulatory agencies, such as Food and Drug Administration (FDA), from time to time in support of investigational new drug applications (INDAs), new drug applications (NDAs), new dosage forms, abbreviated new drug applications (ANDAs), biological license applications (BLAs), and product license applications. For additional information, the reader is advised to check the following website: <http://www.fda.gov/cber/gdlns/stabdft.pdf>.

Prior to the start of a stability study, the pharmacist designs protocols, such as the one shown in Fig. 3. When it is time to initiate a study, the computer is used to generate the stability calendar (Fig. 4). Using this calendar and the protocol, the list of samples for chemical, physical observations, and microbiology analysis of a given time period is generated.

The chemical analysis results and the physical observations are stored in a database for further retrieval. The cumulative chemical data are retrieved in the form of tables for inclusion in a regulatory report (Fig. 5) or for review (Fig. 6). The data can also be presented in a graphic form (Fig. 7), which makes it easy to review large amounts

of data in a short time. Other programs that are used to carry out statistical analysis can access the required data from the stability database. The physical observation data are also presented in the form of tables for reporting and review purposes.

Analytical information systems

The analytical laboratory generates vast amounts of data and information while developing analytical methods, supporting product stability studies, and aiding formulation development. The analytical laboratory needs sample management in addition to the management of data it generates. The analytical systems help by providing lists of samples to be analyzed. These are sorted by project, laboratory location, etc. The system also generates reports of analysis (Fig. 8), cumulative analytical data, and other types of reports needed by an organization.

Quality assurance information system

Several systems are used by the quality assurance unit to help carry out quality assurance functions. One such

system helps the quality assurance function track information on chemical raw materials, package components, intermediate raw materials, and finished products. The information maintained in this system usually includes a lot number assigned in-house, name of manufacturer, date sampled, and type of release and release status. Using other systems, the quality assurance function compares the physical, chemical, and biological test data generated with the specifications established on products or package components and determines whether the product is released or rejected. Production personnel can access these systems online and determine the status of the materials they have produced or determine the status of raw materials to be used in production. A sample output is shown in Fig. 9.

Interactive Voice Response (IVR) Systems

An IVR system is a specially configured personal computer that contains unique voice software that enables a sound-based interface between a user and the system via a telephone. On the most basic level, these systems let

callers exchange information with a computer over the telephone without a human intermediary. Popular applications of IVR systems include banking by phone, flight scheduling, and shipment tracking. In the last five years, IVR systems have gained acceptance in the management of clinical trials. Some of the current uses

include randomization of patients, drug supply inventory management, real-time patient enrollment status, and emergency code breaking in double blind clinical trials. These systems enable the conduct of clinical trials in multiple countries by providing customized voice prompts in various languages.

Group Collaboration Tools

The exponential growth in Internet technologies has allowed companies to set up private Internets, known as Intranets, for effective sharing of information and online meetings where the participants can see each other to collaborate on projects. These tools help to archive project documentation and provide capabilities for searching information across several projects with ease. Some current uses of these tools include collaboration between geographically distributed pharmaceutical R&D and manufacturing plants on process technology data and information.

Document Management and Publishing Systems

In the last 15 years, the size of a typical new drug application has grown from thousands of pages to several hundred thousand pages. To cope with this and to help speed up the submission process, a number of software tools have been developed. These tools provide control and access to documents in a collaborative environment and help publish electronic and paper copies of submissions.

Internet-Based Applications and Tools

Easy navigation of the Internet led to the development of software applications that use web pages for data collection, analysis, browsing, and reporting. As a result, it is becoming easier to deploy software that gathers patient enrollment status information and certain types of clinical trial data. In addition, a number of search tools have been developed that query information across several hundred million pages of information currently available on the Internet. Examples of these tools include Alta Vista, Excite, and HotBot. More information on these tools can be found on www.altavista.com, www.excite.com, and www.hotbox.com.

Project Management Systems

The successful development of a new pharmaceutical product requires careful planning of various activities and resources, as well as tracking the project's progress. A small project is not difficult to monitor manually; however, multiple projects benefit from an automated tool to support the planning process as well as the monitoring of various activities. In addition, these systems will help develop "what if" scenarios for the resources in

the new projects as well as help to terminate the projects. Several project management systems currently available on the market are designed to fulfill these needs. These systems are available for all types of computers—from personal computers to mainframes.

Problem-Solving Applications

The computer is an excellent tool for statistical analysis of data and for solving mathematical problems. Commercial software packages (Table 1) are generally used for statistical analysis. The scientist often works with the statistician to design an experiment and determine the most appropriate statistical method to analyze the collected data. Custom-designed software or commercial software that allows tailoring is generally used to solve mathematical problems.

Spreadsheet Software

This software is available commercially for almost all types of computers and is becoming a valuable tool to solve mathematical problems. The data are entered in the form of tables, the mathematical formulae are defined, and at the push of a button the answer is obtained. The user can easily modify the formula as well as add rows or columns of data and obtain the results easily and quickly. As such, this software enables the user to determine “what-if” scenarios for the problem at hand. It also is extremely valuable in helping the pharmacist compute percent composition and the amount of each ingredient necessary for preparing different strengths of dosage forms. In addition to providing the computational ability, the

software also enables the user to prepare data and information in the form of tables and plots.

Expiry Date Prediction

Expiration dating, required on the label of a drug product by good manufacturing practices (GMPs), is arrived at by analysis of data collected on samples exposed to storage conditions defined in a stability protocol. The establishment of an expiry date has evolved from “eyeballing” the time–temperature plot on graph paper and drawing an approximate regression line, to the rigorous application of physical–chemical laws and sophisticated statistical analysis using computers (1). Using the speed and accuracy available from the computer and expert advice from a statistician, the pharmaceutical scientist can try various statistical models to fit the data and arrive at an optimal expiration date.

Pharmacokinetics

For a number of years, computers have been successfully utilized in pharmacokinetics (2) to: 1) fit blood-level data to the appropriate model (single, two, or multiple compartments) and to calculate model parameters, such as absorption rate constant, elimination rate constant, half-life, and volume of distribution (3); 2) evaluate bioavailability parameters, such as peak plasma concentration, time of peak concentrations, and area under the concentration time curve obtainable from a blood-level curve (4); and 3) calculate dosage regimens in patients with renal failure (3).

Currently, the growing trend is to make use of physiologically–based pharmacokinetic models to study the behavior of drugs in animals and extrapolate the data to humans (4, 5). In this context, computers will be of immense help in developing predictive models that might assist in the scale-up of animal data to humans and predicting the concentration of drugs in human body fluids.

Microcomputers are also used to systematize, speed up formulation, simplify manufacturing processes, and reduce the number of needed bioavailability studies through simulated models and plasma level predictions. Commercially available software packages, such as WINNONLIN, SAS (Table 1), and other custom-designed programs, are generally used to solve the often complex mathematical formulae encountered in pharmacokinetic research and applications.

Communication Aids

The computer has become an excellent tool for communication. It can store information entered by one user and send a signal to another user who then reads the information. When several computers are connected through a network, users of one computer can send information to other users in the network almost instantaneously. This feature makes the computer a powerful and effective communication medium for organizations with various remote locations. Examples of communication aids are discussed below.

Electronic mail

With the proliferation of the Internet, electronic mail (e-mail) has become an integral part of browsers, such as Netscape Navigator and Microsoft Internet Explorer. At times, e-mail software is also bundled into other office automation software packages, such as word processing. This e-mail software allows users to send messages to other users (with e-mail accounts) anywhere on the Internet. In addition to sending mail messages to other users, the software allows the user to file, forward, reply, delete, and print messages sent by others. Most e-mail software packages allow attachment of files that contain text, graphics, video, or audio information. Electronic mail provides almost instantaneous communication to remote users, helps improve the productivity of firms operating on a worldwide basis, and improves communication with regulatory agencies.

Distributed information management systems

A pharmaceutical company with different geographic locations often has a need to communicate between locations in order to share data and information. Using the concept of distributed data processing, the company sets up a data processing center at each location and connects these centers by networks. In this setup, common data management systems running at each site make it easy for the company to work on the same project at several sites and funnel the information back and forth. For example, a company conducting toxicology or stability studies can consolidate the information at one site and use it for generating regulatory reports or for other purposes. In addition, these systems help transfer technology developed at one site to another site and allow access to data generated from other sites.

Laboratory Automation

Many laboratory instruments available on the market today contain built-in microprocessors that process data

collected on samples and display or send the answer to a computer. In addition, they may have an interface that attaches to an external computer for processing the data generated by the instrument. With regard to experiments or analyses performed frequently, it is often desirable to interface the instrument to a computer to aid in the subsequent analysis of data. Some of the commonly encountered systems following.

Chromatography systems

The computer has become a valuable tool in automating chromatographic techniques, especially high-performance liquid chromatography (HPLC). Prior to automation, strip chart recorders were used to record the analog signals from an HPLC detector, and the calculations were done manually. In automated systems, the output from an HPLC detector is digitized through an analog-to-digital (A/D) converter, the digitized information is stored in the computer, and the data is analyzed to compute the final result. The inherent disadvantages associated with a strip-chart recorder are overcome in automation because the computer enables the analytical chemist to change calculation parameters (e.g., the base line, peak start, and peak end) as needed. As a result, the number of repeat analyses to be performed is minimized. The computer, utilized as a systems controller, is especially useful in applications that require techniques such as column switching and solvent gradients.

Automated dissolution systems

The application of computers to solid dosage form dissolution allows for nearly complete automation. Analyst intervention is limited to the analysis setup. The computer executes all other steps by controlling the system devices, such as the sampling pump and the spectrophotometer generally used for analysis. Typically, a fraction of the sample solution is pumped into a spectrophotometer flow-through cell, where its absorbance is measured. The computer uses the absorbance reading to perform calculations and reports the analysis results in a tabular or graphic format. Sampling, analysis, quantitation, data handling, and reporting are all performed by the computer according to the analysis parameters specified before each run or included in a setup table (6). Automation has played a key role in the development of dissolution systems, which attempt to simulate changes in pH in the gastrointestinal tract or the presence of bile salts (7).

Microprocessor-based balances

Microprocessor-based balances are used in the pharmaceutical industry for automating a number of routine operations. Some organizations use these balances to

automate the United States Pharmacopoeia (USP) weight variation test. In this application, the printer attached to the balance prints a hard copy of the individual weights of the dosage form as well as the average and standard deviation (8). The balances are also used in the toxicology and pathology laboratories to weigh animals or organs and then transmit the information to a central computer for further processing.

Process Control

Computerized process-control systems are used to measure process variables through sensors at predefined intervals, make appropriate decisions, and take appropriate actions to keep the process under control. In an open-loop process-control operation, the computer records sensor readings, compares readings against standards, and notifies human operators of needed actions to regulate devices. In more complex closed-loop process-control operations, the computer records the measurements, makes the comparisons with standards, and transmits signals to the regulating devices to make the necessary changes (9). The automation of process control is often limited by the availability of pharmaceutical processing equipment. To date, a number of companies have succeeded in implementing the process-control applications. Two examples are automated tableting and automated freeze-drying.

Automated tableting

Instrumented tablet presses with computer interfaces allow the pharmaceutical scientist to study the mechanism of compaction and the relationship of the mechanism to tablet-compaction properties and formulations. In addition, automated systems are useful to develop compression profiles for reference purposes, to control weight of tablets during development and production, and to monitor punch wear. This automation reduces the burden on personnel faced with the requirements of quality control (10). Merck Sharp and Dohme's major production facility in the United Kingdom is fully computerized to manufacture a high-volume tablet product as well as multiple-tablet products (11).

Automated freeze-drying

Pharmaceutical or biological products that are unstable in solution form are converted to a stable solid state using the freeze-drying technique and later reconstituted prior to administration to a patient. Freeze-dryer equipment manufacturers are now upgrading their equipment with automated control systems. Typically, the automated control system has a personal computer and a programmable

logic controller. The personal computer is used to initiate the process, monitor the process, maintain recipes, and archive data. The programmable logic controller is used to control the freeze-drying, sterilization, and cleaning process by means of instructions downloaded from the personal computer.

The computer is useful in avoiding long freezing times since it is possible to monitor product temperature with ease, and eliminate the need for human operator intervention during transition from one freeze-drying phase to the other. The computer also helps in process documentation and in developing cost-effective freeze-drying profiles that should be useful in scaling up a product from the pilot plant to the production area.

Regulatory Issues Affecting Use of Computers

As previously described, the use of computers and computerized systems in the pharmaceutical industry is growing at a rapid rate. Some of the systems used in the industry range in complexity from the use of personal computers for performing simple tasks (word processing, e-mail, Internet access) to the use of powerful computers in process-control applications. In addition, to help eliminate or reduce paper usage, the pharmaceutical industry has implemented a number of electronic batch record systems in drug substance and product manufacturing to keep track of process documentation.

As the regulatory authority, FDA wants the computerized systems to be validated and requires manufacturers to comply with regulations that cover electronic records and signatures (see http://www.fda.gov/oralcompliance_ref/part). The FDA's *General Principles of Validation Guideline* (12) defines validation as establishing documented evidence that provides a high degree of assurance that a specific process will consistently produce a product meeting its predetermined specifications and quality attributes. This definition applies to computer systems as well as to the processes. To date, the industry has done a good job in validating computerized systems and is beginning to address the implications of electronic records/signature rule. For additional information on computer systems validation and guidance on electronic records and signatures, visit <http://www.pharmaportal.com/articles/pt.fda99.cfm>.

Future Trends

The computer provides solutions to problems that can be defined in a language it understands. Although the computer works faster than humans, it still lacks the

human qualities of intuition, insight, and experience. A great deal of effort has been expended in the development of computer languages and software tools that allow for ease in writing programs and obtaining desired solutions. In spite of this, researchers still need programmers to translate their requirements to the computer; it is probably unrealistic at this time to assume that they can do away with programmers. The challenge facing scientists today is to determine ways in which to help nonexperts accomplish sophisticated tasks with computers. In this regard, Internet technologies have helped a great deal by implementing simple-to-use and standardized navigation techniques for accessing and interacting with information on a personal computer. Any savvy Internet user can now buy airline tickets, shop for electronic items, and search the Internet for information on diseases, product specifications, etc. This trend will continue for the foreseeable future.

Human genomics is another area that is beginning to benefit from the use of computers. Researchers have just begun amazing discoveries in this particular field. As more information on the human genome is discovered, we will begin to understand human diseases at a gene level, thus allowing researchers the opportunity to discover cures for deadly diseases.

Michael Cory

GlaxoSmithKline, Research Triangle Park, North Carolina, U.S.A.

INTRODUCTION

Drug discovery and development are extremely time-consuming and costly processes. For every drug that reaches the market, there are more than 10,000 compounds synthesized, characterized, and tested for biological effects. Hundreds of millions of dollars are invested in the basic research and clinical studies which lead to its FDA approval and subsequent marketing. Traditionally, drugs have been "discovered" predominately through random or targeted screening efforts, followed by discrete structural changes in the molecule to optimize the properties responsible for the desired activity. With rapidly increasing costs, diminishing resources, more intense public scrutiny, greater government regulations, and higher expectations, this hit-and-miss approach is neither efficient nor economical.

The development of new medicines has been and continues to be a spectacularly successful scientific endeavor. While the traditional preparation and modification of complex pharmaceuticals has been a laudable achievement of synthetic medicinal chemists, the advent of computers has ushered in a new exciting approach to drug discovery. The new drug discovery activities, including that of computational chemists, have grown out of these technology changes. One of the clear trends of science has been the reduction of chemistry to particles in motion. Molecules undergo rapid translational, rotational, vibrational, and bending motions, which, in most cases, can be quantified using theoretical physics. Chemical reactivity may be attributed to these dynamic features of molecules. There is a direct relationship between molecular structure and biological activity. Through an intimate understanding of such molecular behavior, the medicinal chemist has the ability to gain profound insights into the most probable drug conformations, as well as the structural and energetic factors responsible for favorable drug-receptor interactions. With a combination of experimental data and computer-based information, the medicinal chemist is in a much better position to predict drug action. Unlike hand-held mechanical models,

computer-generated structures add a new dimension to chemical perception by including the energy for a specific conformation defined by the Cartesian coordinates, which define the molecular array. Of course, other factors such as administration routes, absorption, distribution, metabolism, and elimination (the domain of pharmacokinetics) affect the activity of drugs and are increasingly being considered in the early phases of drug design.

The past twenty years have seen the development of a number of new approaches to drug design. The increased processing power of computers and the rapid display of computer-generated structures is simply amazing since the first writing of this article approximately a decade ago. These exciting developments over the last two or three decades have allowed the emergence of sophisticated computer programs specifically designed to assist medicinal chemists in developing new drugs. The combined application of molecular graphics, computational chemistry, as well as chemical and biological information is commonly called computer-assisted drug design (CADD). These computer-based approaches promise to fulfill a long-coveted goal of medicinal chemists: the prediction of biological activity prior to extensive laboratory synthesis and biological testing. One day it may not be unreasonable to expect medicinal chemists to design active molecular structures in a fashion analogous to the way engineers plan buildings, although the problems associated with biological problems are much more complex and frankly less understood. Computer-aided molecular modeling methods are still in their infancy, with exciting new methods and applications being reported at a staggering rate. Nevertheless, CADD approaches have already had a substantial impact on pharmaceutical design, discovery, and development, moving from the realm of after-the-fact rationalizations to a more beneficial predictive role.

This article will provide a brief introduction to computational chemistry, molecular modeling, and CADD theory. Clearly, it is impossible to cover in this short review all of the useful and/or interesting CADD approaches. Although this is relatively a new field of

research, there are many examples from which to choose. Today, there are a number of pharmaceutical agents in various stages of clinical trials and/or on the market in which computer-based methods were used. Research examples have been included to illustrate more completely the conceptual points. Some of the fundamental methodologies are discussed, including the important underlying mathematical formalisms. In addition, historical perspectives have been incorporated. Finally, the ever-changing hardware and software trends are discussed.

METHODS

Molecular Modeling

Molecular modeling of organic compounds has a long history. John Dalton (1) had a set of wooden spheres, representing atoms, drilled to receive rods representing bonds. These original ball-and-stick models are on display at the London Museum of Science and date to 1810. The most widely known recent application of molecular modeling to the solution of a significant organic chemistry structural problem is the Nobel prize-winning work of J. D. Watson and F. H. C. Crick for the development of their model for the structure of DNA. Initially, Watson and Crick used homemade molecular models cut by hand from cardboard. Later, as they improved their understanding of the structures and the conformations of the bases in the nucleic acids, they had more exact models machined from metal. At the time of their work (mid 1950s) controversy existed over the correct tautomeric forms for the heterocyclic bases. Based on old experimental results, the first Watson and Crick models had the incorrect tautomers. After building models with the correct tautomeric forms of the bases, they quickly arrived at a conformation for DNA that not only matched experimental data but also suggested a method by which DNA could be responsible for cellular replication (2, 3).

In the two decades following this landmark work, various types of hand-held models became commercially available, and they have been used extensively by medicinal chemists. The wooden ball-and-stick models frequently used by high school students, as well as the metal Dreiding and Kendrew (4) models (not to mention the plastic varieties), are still quite popular in organic chemistry laboratories. Before the availability of high-resolution computer graphics systems, X-ray crystallographers depended heavily on metal models, including the Kendrew type, for converting computer-plotted electron density maps into physical models that could be used to study proteins.

Linus Pauling, in his early studies of the conformations of the *alpha* helix in proteins, suggested it would be helpful to obtain solid molecular models that would allow modeling of large pieces of a polypeptide structure. This suggestion eventually led to the CPK (Corey, Pauling, Koltun) (5) spacefilling models which are made from plastic and are designed to effectively represent the true size of atoms. These models were designed under the guidance of an IUPAC committee. Their quality and popularity led to their commercial availability (6). Many laboratories used large quantities of these models to assist in drug design and the understanding of molecular shapes. A few laboratories attempted to use such models for the study of proteins and nucleic acids. Due to their tactile properties, these models are excellent teaching tools and led to an easy understanding of problems in stereochemistry and molecular shape. The mechanical stress on the plastic parts, however, resulted in compromising the integrity of models of large molecules. It turned out that the models for large molecules were less useful than computer representations. Further complications arise when attempts were made to simulate ligand-protein (or drug-receptor) interactions. Importantly, there is no possibility of determining accurately the energy differences among various conformations.

The display of molecular representations on a computer screen has been an objective of many computer scientists over the years. Significant decreases in the cost of computing coupled with dramatic increases in the speed and quality of computer displays have led to the increasing use of computer graphics displays for molecular modeling. Graphics displays have grown from the early ball-and-stick ORTEP (7) plots of small X-ray crystal structures to interactive displays that show spacefilling models of entire proteins. Computer-generated molecular displays are not only integral parts of structural biology and structural chemistry research, but they have also moved into the realm of advertising, as seen on the covers of scientific journals and in the many pharmaceutical media advertisements. In other words, computer-generated images not only impart specific and sometimes subtle chemical and biological information not possible to obtain with hand-held models, but they also tend to represent state-of-the-art methods. Most of these developments were driven by the rapidly growing computer-assisted design market, rather than the much smaller chemistry market.

The growth of visualization applications has been boosted by improved computer graphics displays and increasing computational chemistry capabilities, as indicated above. The initial growth of the market was induced through the rapid acceptance of computer-assisted

design in the aircraft manufacturing industry. Until about 1983, sophisticated molecular modeling software was the domain of some academic scientists; most of the advances took place in X-ray crystallography laboratories. The most sophisticated of these displays allowed full three-dimensional transformation of the coordinate display by turning a dial. Custom-designed computer molecular modeling and display software, now available from multiple vendors, allow the interactive manipulation of the display through a joystick, mouse, dial, and/or keyboard commands.

The use of computer-generated molecular models has many advantages over the more traditional manipulation of physical molecular models. Since the molecules are represented in the computer as sets of three-dimensional (3-D) atomic coordinates, a large number of molecules can be handled simultaneously. A feat which is essentially impossible using mechanical models. Any number of computer-generated images can be superimposed and analyzed. These techniques have provided medicinal chemists with information about the relative size and shape of sets of molecules with similar biological properties. The superimposition of different conformations of the same molecule can provide information about the relative space a molecule can occupy. Since the computer maintains a set of coordinates for each of the atoms in each molecule, information about bond lengths, bond angles, and torsion angles of a model can be rapidly obtained. Additionally, nonbonded and direct through-space distances, so important in defining the shape of receptor sites, can also be readily obtained and compared. Moreover, the information can be stored, retrieved, and re-analyzed at later times.

From the preceding discussion, one extremely important aspect of molecular modeling which cannot be overstated: visualization of molecules. When molecular interactions between a drug and its receptor are displayed, manipulated, and rotated on a graphics terminal, researchers can identify important and unimportant molecular interactions. It is through such computer exercises that medicinal chemists can confirm, reject, or develop hypotheses regarding the molecular origins of biological activity. Perhaps one major drawback to computer-generated structures is the fact that one is unable to handle them physically, which could be an artifact of previous experiences with hand-held molecules in sophomore organic chemistry classes. Interestingly, there is a growing trend in organic chemistry education to move toward computer graphic representations of organic structures. On computer graphics terminals, to give the illusion of three-dimensional visualization, a technique

called *depth cueing* is used to shade structures in such a way that objects further away from the viewer are slightly dimmer, while objects that are closer appear brighter. This optical effect works reasonably well. Another stratagem that creates the illusion of three-dimensional perception is to have the molecular structure slowly rotate about its center of mass or slowly rock back and forth. Current technology allows breathtaking stereo viewing of molecular display on desktop computers. An example of this is the crystal-eyes system (<http://www.stereographics.com/>).

There continues to be important developments in the molecular modeling area. The first is the development and use of algorithms that describe the surface area of molecules. Software utilizing these algorithms allows the comparison of computed surface areas. One of the first algorithms to be widely implemented in the study of molecule surfaces is that of Connolly (8). In it, a sphere of a given radius (usually the radius of a water molecule) is "rolled" over a defined surface, usually the van der Waals surface. Wherever the sphere touches the macromolecule, a new contact surface is generated. The display of this surface allows the medicinal chemist to see what should be considered the *solvent accessible* surface. An alternative approach, much more efficient in computational and display time, is to place a dot surface over the molecule and to compute the surface using expanded atomic radii. The more recent implementations of this algorithm display the electrostatic density at the surface. This provides the chemist with a picture of what charge might be exposed to solvent. As applied to drug design, the *solvent excluded* surface allows an indication of the topology of a receptor site. Plotting physicochemical functions, such as the electrostatic potential, on the surface of this model indicates the forces acting upon a molecule that binds to that surface. Today, it is possible to display transparent molecular surfaces rapidly, which gives the impression that the molecular skeleton is suspended in a gelatin-like volume.

The second major change, interrelated to the discussion above, is related to the decreased cost and increased speed of computation. Raster computer displays generated widespread interest in the development of display algorithms for calculating high resolution spacefilling representations of molecules. Many algorithms, motivated in part by the advances in computer technology, were developed to give rapid, high resolution CPK-like displays of molecular surfaces. Most of these systems provide a static display computed from a specific molecular orientation. Real-time, three-dimensional manipulation of these "CPK" models was demonstrated successfully on some systems (9) and is now standard.

Computational Chemistry

Overview

Much of the recent progress in drug design has been based on the fundamental understanding of drug-receptor interactions and the increased availability of high quality structural data. Quantitative correlations have been made between biological activity and molecular properties. Computer experiments offer complimentary means to acquire essential information that may be quite difficult or impossible to obtain empirically. Of course, these theoretical approaches need to be properly calibrated to existing experimental data to insure that if there are any systematic differences they are clearly understood at the outset. No one is seriously suggesting that computer analysis will replace experimental work. The mathematical models presently used are just that—mathematical models approximating complex physical and biological properties. Traditionally, a great deal of attention has been focused on the structural fit between receptors and ligands, like keys within locks. Today, this idea of a lock-and-key analogy is a well-recognized exaggeration since small molecules and receptors are not static structures but constantly changing to adopt new conformations in response to their environment. In considering pharmacodynamic interactions, favorable electrostatic interactions are critically important. Charge density and the complementarity of charges between ligand and receptor are readily accessible to calculation, although there are several different ways to generate charges. Important quantitative structure–activity relationships (QSAR) between nontraditional parameters such as HOMO–LUMO interactions and bond orders have been correlated with biological activity.

Researchers involved in drug design have been criticized for focusing too extensively on the interaction energies governing ligand–receptor binding while neglecting important solvation and desolvation effects and pharmacokinetic effects. These other aspects of drug availability, as well as toxicity, are more complex to model and consequently more difficult to predict. Progress, however, is being made. Until much more research verifies the accuracy of pharmacokinetic and toxicity models, energy-based approaches focused on drug–receptor fitting will dominate. Alternative chemical information based methods will play increasingly important roles in drug design.

Quantum mechanics

History and concepts: In the late nineteenth and early twentieth centuries, the applications of classical

mechanics failed to describe accurately blackbody radiation or atomic spectra (10a, 10b). For nearly two centuries, Newtonian mechanics had been the cornerstone of physics, essentially unassailed and unailing. According to the prevailing attitude among most physicists of the late nineteenth century, all physical theories had been discovered (10a, 10b). The only remaining challenge for future generations of scientists was to refine minor details and extend the accuracy to an additional decimal place. Wein in 1896 and Rayleigh in 1900 had tried to explain blackbody radiation using standard classical methods. Every attempt, however, by theoreticians of the day failed to reproduce all of the available empirical data. This failure of classical physics has been termed the “ultraviolet catastrophe.” It was not until Planck made his revolutionary proposition, that the oscillators themselves needed to be quantized, that a consistent mathematical solution emerged.

Based on the Einstein wave-particle solution for the photoelectric effect, De Broglie was the first to suggest that if particle characteristics were associated with electromagnetic radiation, then matter should also have wavelike characteristics. De Broglie derived a simple relationship (Eq. 1) correlating the wavelike characteristics, λ , with momentum, p . Large objects would have a vanishingly small wavelength. The wavelike characteristics of matter would only manifest themselves significantly at the atomic and subatomic levels since the wavelength is inversely proportional to the mass. The de Broglie equation was used to predict exact diffraction patterns which were later verified experimentally by Davisson and Germer.

$$\lambda = \frac{h}{p} \quad (1)$$

Since matter had wavelike properties, it could argue that there must be an underlying fundamental wave equation governing the behavior of matter. Erwin Schrödinger (11a, 11b, 11c) formulated the celebrated differential equation, which, for chemists, is the basic molecular expression of quantum mechanics. The idea being that if one could solve the Schrödinger equation, then all of the physical properties of a molecular system (or any system of any size for that matter) would be known. Chemistry, and ultimately biology, could be reduced to solving mathematical equations. Another more general formulation of quantum theory, using matrix algebra, was developed independently by Heisenberg and Dirac (12). Both methods have been demonstrated to be equivalent mathematical representations (13a, 13b).

The concept of spin falls naturally out of the matrix mechanics approach, but it is an ad hoc addition to wave mechanics.

To date, quantum theory, despite its many peculiar “nonclassical” microscopic aberrations, has been used effectively to explain experimental observations and to predict accurately physical effects in advance of the experiment. Interestingly, many of the founders of quantum mechanics later rejected it, primarily because it was a nondeterministic theory. The break from their classical mechanics view of the universe appears to have been too severe for them to accept. But a new generation of physicists was prepared to embrace the quantum mechanics and apply the methods to chemical structures. With a series of novel concepts and observations, physics and chemistry were changed forever. From the brilliant work of Schrödinger, de Broglie, Heisenberg, Dirac, Mulliken, Pauling, and many other pioneers, the new quantum chemistry was born.

Methodology: Unquestionably, the application of quantum mechanics to chemical bonding has revolutionized scientific thinking. In fact, the modern theoretical framework of chemistry rests on quantum physics. In principle, the Schrödinger equation may be solved for any chemical system. No prior knowledge of any analogous or related system is necessary. Exactly solvable problems are rare, due to the mathematical complexities; recourse must then be made to approximate methods, and many powerful approaches have been devised. Generally, approximate solutions must suffice for the size of molecules of pharmaceutical interest.

The Schrödinger equation is the starting point for molecular problems (13a, 13b). The symbol \hat{H} is a differential operator called the Hamiltonian operator, which is analogous to the classical Hamiltonian, inasmuch as it is a sum of kinetic and potential energy terms. E is the total energy for the system. The wavefunction Ψ depends on the position of all the particles comprising the system. Born (10a, 10b) proposed that $|\Psi|^2$, and not Ψ , is a measure of the probability distribution of the particles within a molecule. The Schrödinger equation is an eigenfunction, which in its most general form is written as follows (Eq. 2):

$$\hat{H}\psi = E\psi \quad (2)$$

All quantum chemical calculations rely on a very important assumption called the Born–Oppenheimer approximation, which treats nuclear and electronic

motions separately (Eq. 3), and it is discussed in most elementary quantum mechanics textbooks.

$$(\hat{H}_{el} + V_{NN})\psi_{el}(r, R) = E\psi_{el}(r, R) \quad (3)$$

The nuclei, being much heavier than electrons, are considered fixed in space relative to the faster moving electrons. V_{NN} is a function describing the nuclear potential energy and may be factored out of the electronic expression. This uncoupling of electronic and nuclear motion is critical to quantum mechanical formulations. Nevertheless, the Born–Oppenheimer approximation may not be accurate under certain circumstances. Once a nuclear configuration has been determined, the Schrödinger equation is then solved to give the electronic energy for a particular nuclear configuration. The process may be repeated over every conceivable nuclear arrangement. A potential energy surface can then be mapped. The most stable nuclear–electronic configuration has the lowest energy, and it is referred to as the *ground state*. Promotion of electrons to higher energy states, referred to as *excited states*, usually is not of importance in most drug design applications, although there are exceptions. The vast majority of energy computations related to pharmaceutical agents and their design have been carried out on ground state electronic configurations.

In general, quantum chemical calculations may be divided into three broadly defined subdisciplines based on the approaches taken to solve the Schrödinger equation: 1) semiempirical-based methods, 1, 2f) ab initio-based methods, and (c) density functional theory. John Pople, ab initio methods, and Walter Kohn, density functional theory (DFT), received the 1998 Nobel Prize in chemistry for their pioneering work in computational quantum chemistry.

a. *Semiempirical calculations:* Exact solutions to the Schrödinger equation are limited to special cases: a particle in a box, a particle on a ring, a harmonic oscillator, the hydrogen atom, and the hydrogen molecule ion, etc. In an effort to apply quantum mechanics effectively to chemical systems of more practical importance, several simplifying approximations have been made and refined over the years. Early work by Pople and co-workers (14a, 14b, 14c, 14d, 14e, 14f, 14g) led to an approximation called Complete Neglect of Differential Overlap (CNDO). The central idea behind this approximation was to eliminate certain sets or families of two-electron integrals of the following expression (Eq. 4). The solution of these expressions are the most complicated mathematical steps in quantum chemical calculations,

especially when integration is over four different atomic centers a, b, c, and d. The omitted integrals could then be accounted for by adding empirical equations and parameters. Years later, Dewar developed a series of methodologies that approach chemical accuracy (15). These methodologies have been incorporated into a series of computer programs, MINDO (modified intermediate neglect of differential overlap; 16), MINDO/3 (17a, 17b, 17c, 17d, 17e), MNDO (moderate neglect of differential overlap; 18a, 18b, 18c, 18d, 18e, 18f), and AM1 (Austin Method 1) (19). Correlations between drug activity and molecular orbital energies and coefficients have been made (20a, 20b, 20c). These and similar approximations are classified as semiempirical calculations.

$$\Psi_a^*(1)\Psi_b(1)\left(\frac{1}{r_{12}}\right)\Psi_c^*(2)\Psi_d(2) \quad (4)$$

- b. *Ab initio calculations*: The second quantum mechanical approach is based on what is referred to as the *ab initio* method (21). As the name implies, *ab initio* calculations use a nonparameterized method. Strictly speaking, these calculations also have a number of simplifying approximations; but they are much more demanding computationally, as no classes of integrals are eliminated, and consequently are much more expensive. There have been numerous reports and reviews in the literature on *ab initio* and semiempirical calculations, as well as detailed comparisons of the two methodologies (21a, b).

Usually the Ψ function is formulated from Molecular Orbital (MO) theory, where one-electron orbitals are used to approximate the true many-electron wavefunction. It is assumed that each molecular orbital is a truncated linear combination of n one-electron functions, known as the basis set, and are primarily atomic orbitals. This approach is known as the linear combination of atomic orbital (LCAO) method (23a, 23b). The actual functional form of the wavefunction Ψ determines the complexity of the calculation. Boys (24) originally suggested that Gaussian Type (GT) functions may be used to describe Slater Type (ST) functions, which in turn are approximations of the true hydrogenic orbitals. The use of GT functions greatly reduces computational time because they can be solved explicitly. Since GT functions, unlike ST orbitals, do not have a cusp at the origin, they are less accurate. In addition, as distance from the origin increases the GT functions decay too quickly. Nevertheless, despite these limitations, a linear combination of GT functions can be made to fit an ST function.

Pople found that a minimal basis set was composed of a linear combination of three GT functions; they are referred to as STO-3G (25a, 25b, 25c, 25d). Pople also found that more accurate representations may be achieved with more sophisticated GT combinations. The next level of theory splits the outer shell basis functions into two parts, appropriately known as split-level basis sets. In the early 1990s, 3-21G calculations became the new standard (26a, 26b, 26c), replacing the STO-3G formulation. Presently, more complex basis sets have become the new standard. Additional accuracy was achieved by adding polarization functions, which may be denoted by (*). Other conventions are also used: for example, 6-31G* calculations, the new standard, treat the core electrons with six primitive basis functions (27a, 27b, 27c). The outer shell electrons are divided into two parts, which are composed of a set of three GT functions and one GT function, respectively. Finally, a set of six d polarization functions has been added for non-first-row elements (21, 28). The split basis sets and polarization functions add flexibility to the molecule such that the atomic orbitals can more accurately respond to their environment. Polarization of hydrogen atoms is achieved by adding a set of three p orbitals, denoted by a second * (e.g., 6-31G**). The next level of accuracy divides the outer electrons into three sets of Gaussians (29). With the advances in computers, 6-311G* calculations are more economical and becoming more popular.

Quantum mechanical calculations are carried out using the Variational theorem and the Hartree-Fock-Roothaan equations (13a, 13b, 21, 30a, 30b, 30c). Solution of the Hartree-Fock-Roothaan equations must be carried out in an iterative fashion. This procedure has been called self-consistent field (SCF) theory, because each electron is calculated as interacting with a general field of all the other electrons. This process underestimates the electron correlation. In nature, electronic motion is correlated such that electrons avoid one another. There are perturbation procedures whereby one may carry out post-Hartree-Fock calculations to take electron correlation effects into account (31a, 31b, 31c, 31d, 31e). It is generally agreed that electron correlation gives more accurate results, particularly in terms of energy.

- c. *Density functional theory*: Density functional theory (DFT) is the third alternative quantum mechanics method for obtaining chemical structures and their associated energies (32). Unlike the other two

approaches, however, DFT avoids working with the many-electron wavefunction. DFT focuses on the direct use of electron densities $P(r)$, which are included in the fundamental mathematical formulations, the Kohn–Sham equations, which define the basis for this method (33). Unlike Hartree–Fock methods of *ab initio* theory, DFT explicitly takes electron correlation into account. This means that DFT should give results comparable to the standard *ab initio* correlation models, such as second order Møller–Plesset (MP2) theory.

In some ways, DFT may be more easily understood. According to the Kohn–Hohenberg theorem (34), the energy is minimized when the calculated and true electron densities are equal. One important consequence of DFT calculations is that their accuracy corresponds to standard post Hartree–Fock methods. Another consequence of DFT calculations of more practical importance is the reduction in the computation time required to complete a calculation. The time required to complete Hartree–Fock calculations is a function of the number of electrons in the system being examined, and it is proportional to n^4 , where n represents the number of electrons. DFT calculations, also a function of the number of electrons in the system, are proportional to n^3 . (Contrast the time for quantum chemical calculations with those of molecular mechanics calculations, discussed later. In molecular mechanics, the time scales to m^2 , where m is the number of atoms, not the number of electrons. Molecular mechanics is an attractive and accurate alternative for larger molecular systems where it is impossible to use quantum mechanics based methods.) For systems of interest to medicinal chemists, the differences in computer time between DFT or *ab initio* calculations may be the most important factor in selecting which method is used. Although there are more examples of *ab initio* calculations in the literature and consequently more experience with their accuracy and limitations, there is a growing number of DFT calculations being reported.

Molecular mechanics

History and concepts: A complementary approach for molecular structure calculations is available, and it is referred to as the molecular mechanics or force field method; it is also known as the Westheimer method (35). In 1946, twenty years after the impressive development of quantum theory, three papers appeared in the literature which applied *classical* mechanical concepts to problems of chemical interest (36–38). Westheimer investigated the racemization of some optically active biphenyl

derivatives. His work demonstrated the potential usefulness of molecular mechanics. The other two papers were attempts to tackle more complex problems.

The fundamental concepts of molecular mechanics are deeply rooted in traditional chemical thought, which takes the view that molecules may be considered as a series of masses held together by elastic or harmonic forces (somewhat like balls fastened together by weightless springs). The idea central to molecular mechanics theory, concisely stated, is that any deformation of the ball-and-spring model from its *natural* bond lengths (l_0) and angles (θ_0) results in a strain. These deviations from geometric ideality are reflected in a corresponding increase in energy for the model. A set of classical equations are used to describe the motion and corresponding energy of the spring. Hence, with the wealth of chemical information found in the literature, parametrization of these *classical* equations results in the accurate reflection of molecular behavior—that is to say, the potential used to describe the energy surface are generally referred to as the force field. In physics the term *field* traditionally is given to the continuous distribution of some “condition” prevailing through space.

An isolated molecule may presumably adopt various conformations in response to specific intramolecular forces. In general, the total energy of a molecule (E_{total}) may be regarded as the summation of stretching (E_s), bending (E_b), torsional (E_{tor}), van der Waals (E_{vdw}), and electrostatic (E_{ele}) energy components. For more advanced force fields it is crucial for structural accuracy to include various cross-terms ($E_{\text{cross terms}}$), e.g., stretch–bend, torsion–stretch, and torsion–bend, etc., are added to reflect the fact that motions and interactions are coupled to one another. Additional terms may be added, such as hydrogen bonding potentials. One of the fundamental theorems of molecular mechanics is the division of the total energy into separate, readily identifiable parts, as indicated by Equation (5). As discussed previously, deviations from the *natural* geometry is accompanied by an increase in the total energy (E_{total}) of the molecule. The total energy may be viewed as a summation of various energy terms that medicinal scientists feel comfortable in using an visualizing (Eq. 5). A second tenet of molecular mechanics theory concerns the transferability of the parameters used in the individual potential energy terms of Eq. 4. In other words, the parameters used are transferable from one molecule to the next. The continued success of molecular mechanics in treating a wide variety of compounds has justified these assumptions. When several molecular structures are to

be considered together, however, one must obviously think about intermolecular forces as well.

$$E_{total} = E_s + E_b + E_{tor} + E_{vdw} + E_{elec} + E_{cross\ terms} + \dots \quad (5)$$

Some theoretical purists tend to view molecular mechanics calculations as merely a collection of empirical equations or as an interpolative recipe that has very little theoretical justification (39). It should be understood, however, that molecular mechanics is not an ad hoc approach (35). As previously described, the Born–Oppenheimer approximation allows the division of the Schrödinger equation into electronic and nuclear parts, which allows one to study the motions of electrons and nuclei independently. From the molecular mechanics perspective, the positions of the nuclei are solved explicitly via Eq. 2. Whereas in quantum mechanics one solves, Ψ , which describes the electronic behavior, in molecular mechanics one explicitly focuses on the various atomic interactions. The electronic system is implicitly taken into account through judicious parametrization of the carefully selected potential energy functions.

Methodology: The fundamental molecular mechanics formulation may be derived from the expansion of the potential energy function $E(q_1, q_2, q_3, \dots, q_1)$ in a Taylor series about the equilibrium position q_0 , where q represents generalized coordinates (40), yielding Eq. 6:

$$E = E_0 + \sum_{i=1}^n \left(\frac{\partial E}{\partial q_i} \right)_0 \Delta q_i + \frac{1}{2} \sum_{i=1}^n \sum_{j=1}^m \left(\frac{\partial^2 E}{\partial q_i \partial q_j} \right)_0 \Delta q_i \Delta q_j + \frac{1}{6} \sum_{i=1}^n \sum_{j=1}^m \sum_{k=1}^o \left(\frac{\partial^3 E}{\partial q_i \partial q_j \partial q_k} \right)_0 \Delta q_i \Delta q_j \Delta q_k + \dots \quad (6)$$

The first term in the expansion is a constant. Since there is the freedom to select a point of zero potential energy E_0 can be defined as zero. The second term is the negative of the restoring force, which is equal to zero at the equilibrium position (Eq. 7):

$$-F_i = \left(\frac{\partial E}{\partial q_i} \right)_0 = 0 \quad (7)$$

Hence, the first nonvanishing term in the Taylor series expansion is the third term, which is a quadratic expression. This third nonvanishing term corresponds to a Hooke's law potential in the limit of small vibrations. The series may be truncated after the third term to provide the following potential energy expressions (Eqs. 8–10):

$$E_s = \frac{1}{2} \sum_{i=1}^n k_q (q_i - q_0)^2 \quad (8)$$

$$E_\theta = \frac{1}{2} \sum_{i=1}^n k_\theta (\theta_i - \theta_0)^2 \quad (9)$$

Additionally, cross terms such as the stretch–bend potential, shown below in Eq. 10, may be included in the force field equation to give better agreement between experiment and calculation.

$$E_{\text{stretch-bend}} = \frac{1}{2} \sum_{i=1}^n \sum_{j=1}^m k_{\theta} (q_i - q_0)(\theta_j - \theta_0) \quad (10)$$

The stretching, bending, and various cross-term potentials [specifically illustrated with a stretch–bend effect in Equation (10) above] naturally arise from the Taylor series expansion. Cross-terms have been successfully added to various force fields to give more structural flexibility. For example, when intramolecular angles are compressed, experimental studies indicate that the bonds stretch to relieve the strain resulting from the angle bending. Mathematically, in a valence bond force field, this may be incorporated into a force field potential through cross terms. In the case of angle compression and bond stretching, a stretch–bend term may be introduced (see Eq. 10). There are other ways to treat these effects. Explicit terms between 1,3 nonbonded atoms may also be incorporated, and are called Urey–Bradley force fields. The MM2, MM3, and MM4 force fields (41a, 41b, 41c, 41d, 41e, 41f, 41g, 41h, 41i, 41j, 41k) uses stretch–bend cross terms to mimic this type of molecular behavior. In the latest formulation of molecular mechanics treatments, Allinger and co-workers have incorporated a torsion stretch term to represent quantitatively the bond stretching that occurs in strained molecules. It has been shown that some cross terms are more important than others, which means that some can be neglected without drastically affecting the calculated structures. Additionally, certain cross terms are known to affect calculated vibrational spectra.

Higher terms from Eq. 6 may also be added to the simple quadratics to furnish better representations of chemical bonding. Nevertheless, these energy terms alone do not adequately describe molecular behavior.

The third energy term of Eq. 5 arises from pairwise nonbonded interactions summed over every pair i and j . Two opposing forces play a role in this energy term. For relatively long distances, two atoms attract each other due to London dispersion interactions, which are proportional to r^{-6} . As the two atoms come into close proximity, they

exert a mutual repulsion known as van der Waals repulsion. the Leonard-Jones 6–12 potential function [Eq. 11] describes this behavior (42), originally derived for the noble gases, and is most often used in simple force fields. Quantum mechanical calculations indicate that the repulsion part of the curve may in fact be somewhat overestimated. Some force fields use a 6–10 potential to reduce the steepness or hardness of the curve as two atoms approach one another, which is perhaps most commonly used for cases of hydrogen bonding. The use of an exponential term instead of the r^{-12} term in force field equations better reproduces experimental data for organic structures and is more consistent with quantum chemical calculations. Potential exponential functions have been known for some time. In fact, MM2, MM3, and MM4 use a modified Hill equation to determine the nonbonded interactions.

$$E_{vdw} = \sum_{ij} \sum \left[\frac{A}{r^{12}} - \frac{B}{r^6} \right] \quad (11)$$

It has long been known that molecules do not rotate freely. In 1891, Bischoff proposed that ethane preferred a staggered conformation and that restricted rotation occurred in substituted ethanes (43). Christie and Kenner first demonstrated restricted rotation in 1922 by resolving 2,2'-dinitrophenyl-6,6'-dicarboxylic acid into optically active isomers (44). Pitzer showed that the calculated and observed entropies for ethane were identical if restricted rotation was considered (45a, 45b). The phenomenon of restricted rotation appears to be ubiquitous and has stimulated intense interest and research.

There has been much speculation concerning the origin of the internal energy barrier (46). Three explanations which have been proposed: 1) repulsion between the bonds not covered by the van der Waals repulsion; 2) correction

for the anisotropy of van der Waals repulsion; and 3) various quantum mechanical suggestions.

The barrier to internal rotation must be included in the force field. Usually, the internal rotational energy is a function of the torsion angle ω . (See Fig. 1.) Klyne and Prelog have defined the torsional angle ω for the connected atoms A—C—C—D, as depicted previously. Rotation of A towards D along the shortest arc, viewing the molecule along the C—C axis, is defined as a positive value when clockwise.

The torsional potential may be expressed as a truncated Fourier series, as shown in Eq. 12, where the summations is over all n unique bond dihedrals (torsions), ω . Usually, the first three terms are sufficient to describe the torsional energy adequately. Higher terms may improve the fit between experimental data and calculation. Inclusion of V_1 and V_2 terms has improved the agreement between experiment and calculations (35a, 47b, 47c). Radom, Hehre, and Pople (48) had given a physical explanation to the torsional terms. The onefold term, V_1 , is a dipole–dipole interaction. The twofold term, V_2 , arises from hyperconjugation. The threefold term, V_3 , has a steric origin.

$$E_{\text{tor}} = \sum_{i=1}^n \left[\frac{1}{2} V_{i,1} (1 + \cos \omega) + \frac{1}{2} V_{i,2} (1 - \cos 2\omega) + \frac{1}{2} V_{i,3} (1 + \cos 3\omega) + \dots \right]$$

Other related Fourier expressions may include phase angles, which may also be used to describe potential energy curves; this is the approach employed in AMBER (49a, 49b, 49c, 49d). See Eq. 13, where ϕ is the dihedral angle, V^ϕ is the force constant, n is the multiplicity, and δ is the phase angle. These Fourier series expressions allow the incorporation of additional experimental or quantum mechanical phenomena into force field calculations.

$$E_{\text{tor}} = \sum_{i=1}^n V_\phi [1 + \cos(n\phi - \delta)] \quad (13)$$

Electrostatic interactions play a crucial role in the binding associated with drug–receptor interactions. The electrostatic part of any molecular mechanics potential energy expression is extremely important for many types of calculations beyond drug–receptor considerations. Interestingly, consensus opinion on the best formulation has not been reached. It appears that two alternative, but ultimately equivalent, representations may be used: 1) point charge–point charge and 2) dipole–dipole

Fig. 1 Dihedral angle representation.

interaction models. Most force fields utilize the former, explicitly assigning point charges to each atom in a molecule and relying on Coulombic interaction terms, where the energy varies between two point charges, q_1 and q_2 , by r^{-1} . Mathematically, this formulation requires the evaluation of square root terms. Originally when applied to large biopolymers, the electrostatic calculations were quite time consuming. An approximation which successfully circumvents this problem sets the dielectric constant equal to r (50a, 50b): With this stratagem, q_1 and q_2 vary as r^{-2} , and this in effect dampens the charge interactions. The Allinger force fields and the many variants treat electrostatic interactions with a dipole–dipole interaction equation, where the dipole energies vary by r^{-3} . For charged structures, there must be dipole–charge and charge–charge terms. The charges or dipoles are not static, and the recipes are influenced by neighboring groups. Ideally, terms or methods which consider the polarizability of groups are increasingly being used (51). Progress over the years continues.

The treatment of charges in molecular mechanics calculations remains a central question. The exact computational scheme used to obtain charges has been under considerable review. One obvious way is to obtain the charges from quantum mechanics calculations. Since quantum mechanically derived point charges are based on various population analyses, the level of accuracy required and how the charges should be distributed between the atoms have not been universally accepted. One final check on the charge distribution in a molecule is the comparison of the calculated dipole moment with experimentally determined dipole moments. If there is a reasonable charge distribution, based on calculated charges, then the calculated and experimental dipole moments should be in close agreement.

As indicated earlier, molecular mechanics has also been described as the empirical method. Most of the parameters and equations are designed to reproduce experimental data (for example, molecular geometry, dipole moments, and heats of formation). Perhaps the term *empirical method* is becoming outdated. In many cases, high level ab initio (or DFT) calculations are being used to augment sketchy or nonexistent experimental data such as charge distribution, conformational energies, and rotational barriers (52a, 52b, 52c, 52d, 52e, 52f). Recent work by several groups has used a combination of experimental and theoretical work to parameterize transition state force fields (53a, 53b, 53c, 53d, 53e).

Geometry optimization: Once the three-dimensional Cartesian coordinates and necessary parameters (such as atom and/or bond types) have been established for a molecular structure, the next step is to determine the

energy-optimized structure. Various molecular mechanics programs have geometry optimization algorithms built into them, and they are capable of locating an atomic arrangement at an energy minimum. The initial structure has an energy associated with it based on the particular force field. Every atom has a net force acting upon it. The objective is to relieve as many of the forces as possible, such that the derivative of the potential energy equation is zero.

A variety of methods have been developed for these purposes. Most of the modern methods involve differentiation of the analytical functions, whereas earlier methods used numerical techniques to reach the lowest point (bottom) of the potential energy well. These methods assume the potential energy function is well behaved and differentiable. On the one hand, the simplest approach is called *steepest descent* (54a, 54b, 54c). In this method, displacement steps k_i are taken in the direction parallel to the net force acting on the atom. Since the displacement vector is parallel to the force, which in turn is equal to the negative of the gradient of the potential, the direction is straight downhill. Steepest descent is relatively efficient when the geometry is poor, i.e., far from the minimum. As the minimum is approached, however, the derivatives become smaller and smaller. Consequently this algorithm has reduced efficiency in these cases.

On the other hand, conjugate gradient methods (55a, 55b) are more effective in locating the minimum energy structure. In this approach previous optimization information is utilized. The second and all subsequent descent directions are linear combinations of the previous direction and the current negative gradient of the potential function. Conjugate gradient methods are generally more efficient than steepest descent. In general, for an N -dimensional quadratic surface, the minimum will be located in N steps.

The Newton–Raphson approach is another minimization method (56a, 56b). It is assumed that the energy surface near the minimum can be described by a quadratic function. In the Newton–Raphson procedure the second derivative or **F** matrix needs to be inverted and is then used to determine the new atomic coordinates. **F** matrix inversion makes the Newton–Raphson method computationally demanding. Simplifying approximations for the **F** matrix inversion have been helpful. In the MM2 program, a modified block diagonal Newton–Raphson procedure is incorporated, whereas a full Newton–Raphson method is available in MM3 and MM4. The use of the full Newton–Raphson method is necessary for the calculation of vibrational spectra. Many commercially available packages offer a variety of methods for geometry optimization.

In many cases, low-energy conformations are sought, although the drugs bound to receptors are required (and usually are not) in their lowest energy state for the isolated molecule. All of the algorithms, described above, have been almost exclusively designed to find minima, but not necessarily the global minimum. When an energy optimization has been carried out for a complex molecule, it is impossible to tell whether or not the absolute lowest energy conformation has been calculated. In general, programs are not designed to go over energy barriers. The energy-minimized structure depends on the starting coordinates initially used. So if the coordinates corresponding to the boat conformation of cyclohexane were used as the starting point, then the force field optimizer would seek out the closest energy well. In this case, the final geometry would correspond to a twist-boat structure, a minimum, but not the chair form, the global minimum.

As indicated, there is no assurance that the *bioactive* conformation is necessarily the *global* minimum or, for that matter, a minimum at all (57a, 57b, 57c). Nevertheless, the simplifying assumption is that minimum energy conformations are at the very least good starting points for examining potential drug candidates. To alleviate the concern of not finding the global minimum, automated conformational search procedures have been devised. In general, one or more bonds may be rotated and evaluated based on some criterion, such as energy differences and/or van der Waals interactions. From these searches, a series of compounds can be saved in a computer file, retrieved later, and then subjected to energy optimization procedures. The problem with conformational searching techniques is that they are computationally demanding; and, if the dihedral angle increment is too large, one could miss some low-energy conformers. The use of conformational searching formed the basis of the active analog approach championed by Marshall (57a, 57b, 57c).

Molecular simulations

Dynamics: Molecular mechanics calculations treat molecules as static, time-averaged structures. Since there is an exponential growth in the number of conformations with increasing degrees of freedom in a molecule, a systematic search of the configuration space for the low-energy conformations of large molecules is virtually impossible. Another powerful computational method which has been applied to conformational problems is molecular dynamics (58a, 58b, 58c). Molecular dynamics (MD) simulations describe the trajectory (configurations as a function of time) of a system by integration of Newton's equations of motion, where the force on particle

i is represented as F_i . The phase space trajectories generated with MD calculations are analyzed to yield equilibrium and dynamical information. See Equations (14a, 14b, 14c, 14d, 14e, 14f, 14g) and (15), where r represents the position and E the potential energy.

$$\frac{d^2 r_i}{dt^2} = m_i^{-1} F_i \quad (14)$$

$$F_i = -\frac{\partial}{\partial r_i} E(r_1, r_2, r_3, \dots, r_N) \quad (15)$$

This technique, provided a sufficiently good force field has been developed, has certain advantages over molecular mechanics calculations by themselves in that solvation interactions may be determined and different energy minima can be located.

Monte Carlo simulations: The use of Monte Carlo (MC) methods (59) which incorporate the metropolis algorithm has been used the basis for conformational searching (60), drug-receptor docking (61), and free energy perturbation calculations (see next section) (62). MC is based on the principles of statistical mechanics, where an ensemble of molecular states are generated and evaluated. The metropolis MC method for finding available conformations are summarized in the following steps. First, the starting molecular geometry is calculated using a suitable molecular mechanics potential. Second, a small random perturbation is applied, i.e., one of the atoms is kicked from its original position to a new position. Third, a new energy is calculated. If the energy is lower, then the move is accepted, and the new configuration or conformation (which depends on whether the solvent or solute is being perturbed) is stored for later use. If the energy is higher there is a probability that it may or may not be rejected. The probability is based on a Boltzmann factor ($e^{-\Delta E/kT}$), where ΔE is the energy difference between the final and original states ($E_2 - E_1$), k is the Boltzmann constant, and T is the temperature. It is necessary to accept some higher-energy-state configurations or conformations to avoid becoming trapped in a local minimum. The procedure described is repeated for many iterations until the lowest free energy is achieved. MC, like MD simulations, can be used to treat solvation.

Free energy perturbations: One of the challenges facing medicinal chemists is to predict (and ultimately prepare and test) compounds with high affinity and efficacy for target receptor sites. Knowing the free energy of binding, $\Delta G_{\text{binding}}^\circ$ for a series of structurally related compounds is important information. Unfortunately, determining the $\Delta\Delta G_{\text{binding}}^\circ$ for many different analogs is experimentally demanding. Free energy perturbation

Fig. 2 Free energy perturbation (FEP) diagram, showing drugs D and D' binding to receptor R to give the DR and DR' receptor complex and the free energy changes.

(FEP) calculations (63a, 63b) take advantage of the fact that the change in a complete thermodynamic cycle should be zero (see Fig. 1). By measuring the equilibrium constants K_2 and K_1 , the experimental $\Delta\Delta G_{binding}^0$ can be obtained according to Eq. 16. Inspection of Fig. 2, however, reveals that if D_1 could be mutated to D_2 and DR_1 could be mutated into DR_2 , we would have a relationship where knowing the difference between $\Delta^*G_4^0 - \Delta G_3^0$ would be equivalent to $\Delta G_2^0 - \Delta G_1^0$ (Eq. 17). The former relationship can be simulated using either MD or MC methods.

$$\Delta\Delta G_{binding}^0 = \Delta G_2^0 - \Delta G_1^0 = -RT \ln \frac{K_2}{K_1} \quad (16)$$

$$\Delta G_2^0 - \Delta G_1^0 = \Delta G_4^0 - \Delta G_3^0 \quad (17)$$

FEP is a major conceptual achievement with important ramifications for drug design. Unfortunately, two major problems have prevented FEP from being routinely applied to drug design outside of academic research. First, the mutations must be small and gradual. Calculations need to be carried out during the mutations process. Second, the calculations are computationally demanding even on high speed workstations. Nevertheless, it is an attractive computational approach.

COMPUTER-ASSISTED DRUG DESIGN

Computational chemistry applied to drug design relies on two major experimental sources of detailed three-dimensional (3-D) data: 1) X-ray crystallographic analysis and 2) nuclear magnetic resonance (NMR) spectroscopy.

High precision X-ray crystallographic studies now are reported routinely in the literature for small molecules and for proteins and nucleic acids (64). These data provide

spatial locations (3-D coordinates) for the atoms in a molecular structure. Since X-rays are diffracted by electron density, hydrogen atoms are not generally located with the same accuracy as heavy atoms. In general, the crystallographer is able to provide complete structures. In protein X-ray crystallography the knowledge of the amino acid sequence of the protein assists the crystallographer in developing a model of the atomic positions and bonding (65). Backbone traces based on three-dimensional electron density make the viewing easier for macromolecular structures. Interestingly, computer-based approaches are also used to fit experimentally determined electron density maps to proposed structures.

NMR techniques are also being used to determine 3-D macromolecular conformation. High-resolution NMR combined with pulse experiments can provide connectivity information along a protein chain. Nuclear overhauser effect (NOE) signals are sensitive to the through-space distances between atoms, and they can be used to determine the folding pattern in a protein. The combination of connectivity data, NOE-determined distance constraints, and amino acid sequence information provides a molecular modeler with a substantial set of geometric constraints for building models of macromolecules. These constraints can be combined to build a macromolecular model using the mathematical technique of distance geometry.

Distance geometry provides sets of 3-D structures of a protein or nucleic acid that fulfill the constraints. The combination of distance geometry, for generation of molecular starting points, with molecular dynamics computations can yield 3-D models of small proteins with precision equal to X-ray crystallography (66). This combination of NMR, molecular mechanics, and molecular dynamics (67) can be used to provide a three-dimensional protein structure in a situation where the protein cannot be crystallized or the crystals are not appropriate for X-ray crystallography.

The term CADD has been used to describe two aspects of the recent use of computational tools that aid computational and medicinal chemists in the search for new drug candidates. In the first approach, medicinal chemists attempt to describe the predominant statistical correlation of biological activity with directly measurable physico-chemical parameters or characteristics of drugs and is known as Quantitative Structure-Activity Relationships (QSAR) (68). The central idea is that compounds exhibit biological activity based on structural characteristics. It should then be possible to correlate the associated biological activity with various critical parameters. In general, the biological activity may be considered a function of hydrophobicity, electrostatics, and steric forces (Eq. 18).

$$\begin{aligned}\text{Biological Activity} = & f(\text{hydrophobicity}) \\ & + f(\text{electrostatics}) + f(\text{sterics})\end{aligned}\quad (18)$$

The seminal work of Corwin Hansch initiated the field of QSAR (69). Two-dimensional and three-dimensional QSAR methods (2-D QSAR and 3-D QSAR) have been widely applied to problems of biological interest. The latter approach has increased in popularity with the introduction of the comparative molecular field analysis (CoMFA) (70) and commercial availability of similar methods.

The second aspect of CADD relates more closely to computer modeling. This approach can be characterized as pharmacophore mapping, which uses structural information from receptors or small molecules (in combination with computational chemistry techniques) to develop new candidate drug targets. A pharmacophore, first defined by Paul Erlich, is the set of essential molecular features in a compound responsible for a specific pharmacological action. This approach has also been called receptor-based drug design, using a very general definition of the word receptor (71), which broadens the definition of classical pharmacology. In this technique, a receptor or a model of a receptor is used as the target for the drug design efforts. This receptor model can be an X-ray crystallographic structure or a model built from the X-ray structure of a homologous protein. These can be viewed as recognition sites, since it could be argued that the receptor *recognizes* certain patterns of geometry and charge density of a drug as it approaches and binds to its receptor. As improved computational and X-ray structural tools

become available, modeling of pharmacophores in 2-D as well as in 3-D, also an old technique, has become a more commonly used and much more sophisticated approach.

Some early pharmacophore models contained sets of hexagonal rings (72) presented as a single plane. These rings were used to describe, in a 2-D fashion, the relative 3-D relationship of receptor functional groups. If no receptor surfaces are known to exist in a specific orientation, this area is called a "bulk tolerance area" of the unknown, but complex, 3-D area of an enzyme's active site (73). Another later example of pharmacophoric models is the triangular N O O hypothesis which Cheng (74a, 74b) used to describe, in simple geometric terms, the conformation of active antitumor agents. This hypothesis used early results from X-ray crystal studies on small molecules and measurements from physical molecular models to suggest the required geometry of active antitumor agents. Through-space distances were used to connect a basic nitrogen with two hydrogen-bond-donating oxygen groups. This pharmacophore model was more sophisticated than most previous models because it was developed with three-dimensional data.

More recently CADD software, for example the Catalyst program from MSI (www.msi.com) (75, 75), is available for pharmacophore modeling and searching of 3-D databases. The use of such a program, only one of many with similar power, shows the increasing sophistication of computational search strategies for drug design and discovery. The input to this program is a structure activity set of molecules. The program then analyzes the set of molecules and generates a set of pharmacophoric hypotheses that can be represented in 3-D. The

Fig. 3 Three-dimensional pharmacophore generated in catalyst.

pharmacophoric hypotheses can then be used by catalyst to search databases of molecule for pharmacophore matches.

Fig. 3 represents an example of a 3-D pharmacophoric hypothesis as generated in catalyst. This is a 2-D snapshot of the 3-D pharmacophores. They would have inter-pharmacophore distances associated with the computer data object. The blue plane represents the location of a plane of an aromatic ring with the necessary perpendicular vector for orienting aromatic ring systems in new molecules. The smaller of the green spheres represents a hydrogen bond acceptor, sized at 1.7 Å, and the larger sphere representing the projected point and locations for a possible hydrogen atom donating group with a sphere of 2.3 Å. The red sphere represents a positively charged group with a radius of 1.5 Å. This type of pharmacophore hypothesis can then be used as a 3-D search query that, in many cases has proven useful in finding molecules related to the initial input set.

As previously mentioned, X-ray crystallography provides the bulk of the 3-D information used by medicinal and computational chemists in structure based drug design. Two research-based organizations (76, 77) have compiled and provided a subscription service to databases which are the primary source for X-ray structural data. Besides the information contained in the databases, the existence of these organizations and defined computer formats for crystallographic data has the advantage of providing the scientist with some standardization. Commercial molecular modeling software packages provide a transparent interface between graphics display programs and these data. The two databases divide their holdings on the basis of the size of the molecule. Large polynucleotide crystal structures and structures with drugs bound to polynucleotides are stored in both the protein data bank (PDB <http://www.rcsb.org/pdb/>) and Cambridge files, with the division basically being subjective. Generally, the larger structures are in the PDBdatabase.

The Cambridge Crystallographic Data Center (<http://www.ccdc.cam.ac.uk/>) (76) now provides a computerized database of more than 200,000 small molecular structures. In addition to this extensive structural database, the Cambridge group has developed a suite of programs for systematic structure search and retrieval. The most unique aspect of these programs is that database search queries can specify desired structures in three dimensions.

With the rapid advances in macromolecule crystallography, the PDB (<http://www.rcsb.org/pdb/>) (77) currently contains about 12,600 macromolecular NMR or crystal structures. While this may not represent all macromolecular structures, it does represent the large majority. Most of the major scientific journals require simultaneous deposition of macromolecular crystal data into the PDB as the journal article is published. Besides structural proteins, and the classic crystal structures such as hemoglobin and lysozyme, the data base includes many enzymes or representative enzymes from classes that could be good targets for chemotherapy.

Table 1 shows a realistic overview of the successes of CADD in the pharmaceutical industry. Target proteins have been vigorously explored as indicated by the number of structures in the PDB. The only criteria of success that can be used in this situation is to measure compounds put into clinical trials, since about 80% of candidate drugs fail in clinical trials many of these compounds may not end up on the market.

Automated X-ray diffractometers integrated with fast computer workstations are commercially available for rapid acquisition of protein diffraction data. Area detectors for X-ray diffraction allow for rapid collection of much larger quantities of reflection data and provide the ability to find structures for materials that were too unstable to withstand the older, slower techniques. New automated software routines that use direct methods allow companies to provide a commercial service solving crystal structures. Increasing use of synchrotrons around the world has

Table 1 Overview of the success of CADD

Target (# in PDB)	Research group	Method	Outcome
Thrombin (105)	Hoffman-La Roche	X-ray, models (2.2 Å)	Clinical candidate
Thrombin	Biogen Inc.	X-ray, models	Phase III
Neuraminidase (53)	Monash University/GW	GRID search, X-ray (2.4 Å)	Phase II*
Purine nucleoside phosphorylase (16)	Biocryst	Molecular mechanics X-ray (1.5–2.0 Å)	Phase II
Thymidylate synthase (66)	Agouron	Modeling X-ray (1.9–2.5 Å)	Clinical candidate
Carbonic Anhydrase (111)	Merck	Multiple X-ray (1.9–2.5 Å)	Market
Rhinovirus-14 (28)	Sterling Winthrop	Screening X-ray (2.9 Å)	Phase I
Aldose reductase (13)	Ayerst	Molecular orbital QSAR (1.8–2.3 Å)	Market

allowed rapid collection of X-ray data. The technology has expanded widely into the pharmaceutical industry. Consortia such as IMCA provide drug discovery with a significant resource for crystallography. (<http://www.imca.aps.anl.gov/>)

STATE-OF-THE-ART COMPUTER-ASSISTED DRUG DESIGN

Theory

Most recently an interesting model for approaching CADD has been presented (78), where a set of guidelines for the practical application of CADD techniques are provided. It relates the number of compounds that need to be investigated in a drug-discovery project to the amount of information available about the drug target. More information, available about the target, means that fewer compounds must be investigated in the drug design process and also changes the techniques used by the computational chemist. This is illustrated graphically in Fig. 4.

On the one hand, if the protein X-ray crystallographic structure has been characterized, then the techniques of CADD are used directly. This would involve use of the crystal structure as a target of design efforts using the structural information. That initial effort would be followed by solving additional structures with new, more potent, ligands bound to the protein. The bound structures are modified, graphically, and then evaluated using methods previously discussed. Only compounds that show promise as possible ligands are actually prepared. On the other hand, if there is less information about the target available: 1) a protein sequence and no characterized structure or 2) a set of compounds with different degrees of biological activity. Then the pharmacophoric model and hypothesis approach, discussed above, can be used. A 3-D pharmacophoric model building effort, using

catalyst might develop pharmacophore models that can be used to search libraries of structures.

At the other extreme if you have no knowledge of the protein structure, no candidate ligands, and the X-ray structure is not yet known then a high throughput screening of primary large scale collections of compounds or combinatorial libraries would be screened. These techniques would use roboticized and miniaturized assays and be done to search for possible binding compounds.

Methodology

Design of enzyme inhibitors guided by molecular modeling and X-ray crystallography

An excellent, and successful, structure based drug design example in a system where there is significant structural information is work on the development of new inhibitors of HIV protease (79a, 79b). This work was carried out by scientists from Dupont Merck Pharmaceuticals. A substantial amount of structural data has been available for a decade on the structure of HIV protease (80).

HIV protease is one of the proteins coded by the HIV viral genome and expressed as part of the reproductive cycle of the virus. HIV protease contains active aspartic acid residues that classify it as an aspartyl protease. The viral genome once incorporated into the host genome codes for a polyprotein. The protease is responsible for cleaving specific sites in the polyprotein into specific proteins that allow the virus to mature. The HIV protease is a symmetrical dimer of with each monomer containing 99 amino acids. Fig. 5 shows a cartoon of the protease structure with the active site region labeled. This region is responsible for the binding of the protein substrate sequence. It recognizes and binds a hexapeptide and hydrolyzes the labile central peptide bond.

Fig. 6 shows the binding mode of an HIV protease inhibitor from a X-ray study (file 4phv). In this figure two amino acids, glycine 49 (GLY49) and isoleucine 50 (ILE50) of the HIV protease, are shown in stick form. The remainder of the protein-active site is in line form. Since the enzyme is a symmetrical dimer, the residues from each dimer are shown although only one pair of residues is labeled. Also shown is a water molecule bound in the active site of the enzyme. It is believed that this water molecule assists in the peptide bond hydrolysis. The protein NH groups bind to this water molecule. Carbonyl groups of the inhibitor also interact with this water molecule. Additionally this crystal structure shows the position of the peptidomimetic, HIV protease inhibitor, **1**, and the manner in which the four aromatic ring systems fit into the enzyme.

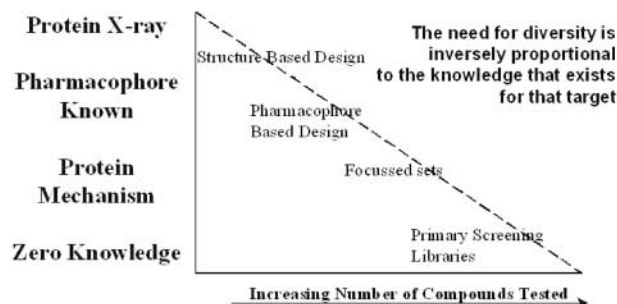

Fig. 4 Plot of relationship between information and number of compounds necessary for synthesis.

Fig. 5 HIV protease structure with active site region labeled.

The second structure in Fig. 6 represents a similar view of the crystal structure (file lajx). In this structure-based design, a cyclic urea 2 was synthesized in which it was hypothesized that the water molecule could be replaced by a functional group of the inhibitor (81). In the case of compound 2, the oxygen of the water was replaced by the oxygen of a carbonyl group that interacts with the backbone NH groups just as the water molecule does. The four aromatic groups of the cyclic urea structure.

Equipment

Currently, molecular modeling hardware is concentrated on two groups of computer systems. High-end

Structure 1.

workstations with high-resolution graphics display systems for molecular modeling are primarily Silicon Graphics models, running the Silicon Graphics version of the UNIX operating system. These systems have held predominance in the market for about a decade. A rapidly growing competitor is the standard Intel chip powered, PC running Windows or Windows/NT. The vast majority of the pharmaceutical industry has supported Windows/NT desktops for scientists. Marketing efforts by computational chemistry software vendors have been shifting rapidly to that arena.

While there is considerable press about the Linux version of UNIX, it has still not penetrated the computational chemistry market to a large extent. Future high end computing will probably depend upon versions of UNIX with transparent delivery to desktop workstations.

Fig. 6 X-ray structure of HIV protease and protease inhibitor taken from PDB.

Fig. 7 X-ray structure of cyclic HIV protease inhibitor with carbonyl group mimic of water.

Software

The emergence of molecular modeling and computational into a discipline has been closely associated with advances in computer hardware, computer graphics, and software. The availability of more sophisticated number-crunching power has allowed scientists to calculate the properties of larger and larger molecules. With the advent of supercomputers, dynamics calculations on biomolecules surrounded by an environment of water are becoming common.

The advances in software have also been spectacular. It was not terribly long ago when medicinal scientists were happy to get a color picture that somehow conveyed a three-dimensional perspective. Now software packages allow chemists to conveniently overlay a series of structures and do real-time rotations. Many companies have emerged, most originated by academicians, which

specialize in designing and marketing modeling software. The origins of much of the available software can be traced to university research laboratories. Although many of the packages have similar features and capabilities, they each have a characteristic style, which reflects the philosophies of the developers.

CONCLUSIONS AND FUTURE TRENDS

Chemists have long been associated with ball-and-stick mechanical structures, and the concepts for molecular modeling have been appreciated for a number of years by medicinal chemists. The precomputer modeling endeavors of Pauling and Watson and Crick demonstrated the utility of these methodologies. The mathematical formalisms for quantum and molecular mechanics were worked out years ago; however, the lack of sufficient computational means prevented practical applications. The explosion of modeling endeavors today is directly related to the advent of powerful new computers and algorithms. Now, larger and larger structures can be subjected readily to the rigors of calculations. More realistic simulations, including solvent interactions, can be treated. Molecular structures can be easily displayed and manipulated on computer graphics terminals. The full impact of high-speed desktop workstations, the Internet and the genome initiative.

Structure 2.

Computational chemists, medicinal chemists, and pharmaceutical scientists face an exciting future, as the computer-assisted approaches for drug design are becoming more powerful and more accessible. Every major pharmaceutical company has invested resources into these new tools. Education in the techniques, scope, and limitations are ever increasing. Improvements in the methodologies and computational resources will undoubtedly increase. Nevertheless, biological processes are still poorly understood, for the most part, at the molecular level. Many challenges remain, and theoretical and experimental work will remain tightly correlated in drug design and discovery.

Computer Systems Validation

Orlando Lopez

Johnson & Johnson, NCS, Raritan, New Jersey, U.S.A.

INTRODUCTION

Computer systems validation, as established in *21 Code of Federal Regulation* (CFR) Part 11.10(a) and defined in the recent draft United States (US) Food and Drug Administration (FDA) guideline,^[1] is one of the most important requirements applicable to computer systems performing FDA-regulated operations. It involves establishing the conformance to the intended use, user, regulatory, safety, and function allocated to the computer system.

Similar to any FDA-regulated products, quality is built into a computer system during its conceptualization, development, and operational life. The quality of computer systems cannot be tested after being developed. In addition to software and hardware testing, other verification activities include code walkthroughs, dynamic analysis, and trace analysis. The documentation generated during the validation can be subject to examination by FDA field investigators. The results of a high-quality validation program can ensure with a high degree of assurance the trustworthiness of electronic records and computer systems-related functionality.

OVERVIEW

The introduction in 1997 of 21 CFR Part 11, Electronic Records, Electronic Signatures Rule (hereafter referred to as Part 11) provided the formal codification applicable to computer systems performing FDA-regulated operations. One fundamental principle in Part 11 is that it requires organizations to store regulated electronic data in their electronic form once a record is saved to durable media, rather than keep paper-based printouts of the data on file, as had been the long-term practice in organizations performing regulated operations.^[2] If information is not recorded to durable media, the stored data will be lost and they cannot be retrieved for future use. If “retrievability” is an attribute, then procedural and technological controls contained in Part 11 are essential to ensuring integrity. The implementation of procedural and technological controls to achieve compliance with Part 11 shall be monitored during the SLC.

The approach to be used in covering computer systems validation is by presenting key elements applicable to

any development/maintenance methodology. It is not intended to cover everything that computer system validation should encompass, including Part 11. A wide range of information about computer systems validation is listed in the bibliography.

KEY VALIDATION ELEMENTS

The key elements required to successfully execute computer system validation projects are as follows:

- Selection of a development/maintenance methodology that best suits the nature of the system under development.
- Identification of operational functions associated with the users, operational checks, regulatory, company standards, and safety requirements.
- Selection of hardware based on capacity and functionality.
- Inspection and testing of the operational functions.
- Identification and testing of “worst case” operational/production conditions.
- Reproducibility of the testing results based on statistics.
- Documentation of the validation process.^[3]
- Written design specification that describes what the software is intended to do and how it is intended to do it.
- A written validation plan based on the design specification, including both structural and functional analysis.
- Test results and evaluation of how these results demonstrate that the predetermined design specification has been met.
- Availability of procedural controls to maintain the validation state of the computer system and its operating environment.
- Any modification to a component of the system and its operating environment must be evaluated to determine the impact to the system. If required, qualification/validation is to be re-executed totally or partially.

Selection of a Development/Maintenance Methodology

The SLC is the “period of time that begins when a product is conceived and ends when the product is no longer available for use.”^[4] Certain overall discrete work

products are expected when evidencing the development and maintenance work of computer systems compliance to regulatory requirements. Refer to "Documentation of the Validation Process." The selected SLC specifies the overall periods and associated events. Different system acquisition strategies and software development models can be adapted to the SLC depicted in Fig. 1.^[5] The SLC model focuses on software engineering key practices and does not specify or discourage the use of any particular software development method. The acquirer determines which of the activities outlined by the standard will be conducted, and the developer is responsible for selecting the methods that support the achievement of contract requirements. A modifiable framework must be tailored to the unique characteristics of each project. The SLC includes the following periods:

Conceptualization.
Development.
Early operational life.
Maturity.
Aging.

Project Recommendation, Project Initiation, Release for Use, and Retirement are events. These events are considered phase gates or major decision points, which include formal approvals before the development can proceed to the next period.

The development methodology associated with the SLC is a structured process that decomposes the engi-

neering tasks and associated work products in support of the computer system validation effort. It breaks down the systems development process into subperiods, containing specific inspection and testing tasks that are appropriate for the intended use of the computer system. During each subperiod, detailed discrete work products are developed. This approach leads to well-documented systems that are easier to test and maintain, and for which an organization can have confidence that the system's functions will be fulfilled with a minimum of unforeseen problems.

The most common development methodologies are the Waterfall Model, Incremental Development, Evolutionary Model, Object Oriented, and Spiral Model.

A critical component of the validation process is providing assurance that the development/maintenance methodology is being followed. The SLC and associated development/maintenance methodology applicable to computer systems performing regulated operations shall be specified in procedural control(s). A project team should have the authority to select a developmental/maintenance methodology that best suits the nature of the system under development/maintenance and that is different from the one included in the related procedural control. If this is the case, the selected development or maintenance methodology must be explained in the validation plan.

It is the objective of FDA-regulated companies to select the appropriate SLC and associated development/maintenance methodology. Development and mainten-

Fig. 1

ance teams shall receive adequate training in the use of the chosen methodology.

Identification of Operational Functions

Using a structured process, the goal of the Development Period is to specify, design, build, test, and install the application to be automated or updated. One of the deliverables of the Development Period is the written and approved operational functions (e.g., user's, functional, design) that describe what the application is intended to do.

A key activity to identify operational functions is by gathering systems requirements. The term "requirement" defines a bounded characterization of the scope of the system. It contains the information essential to support the operation/operators. These requirements include functional capacity, execution capability, safety, operational, installation, system maintenance, and regulatory compliance.

The refined scope is captured in the requirements specification, which describes what the system is supposed to do from the process/user's/compliance perspective. The requirements specification is used as part of the framework to select the computer technology supplier and/or contract developer. The system functionality must be well defined at the outset in order to provide the prospective supplier/integrator with enough information to provide a detailed and meaningful quotation. The requirements specification is used to develop the performance qualification (PQ) protocol.

The requirements specification addresses the following:

- The process to familiarize the developer with the user, process and data acquisition requirements, and special considerations of the project.
- The scope of the system and strategic objectives.
- The problem to be solved.
- Process review and sequencing, as well as where each operation is to be completed.
- The direction to solve the problem (e.g., device driven or may just be the mode of presentation of data, data security, data backup, data and status reporting and trending).
- Redundancy and error-detection protocol.
- Environmental control.
- Interfaces (e.g., to field devices, data acquisition, reports and HMI), input/output (I/O) list, communication protocol, and data link requirements.
- Type of control/process to be performed.
- Operational checks and sequencing.
- Data management.

- Definition of the input and output domains.
- How the data are to be collected, used, and stored.
- How input data influence the operation of the system.
- Retention requirements.
- Data security requirements.
- Audit trails and metadata.
- Timing requirements.
- Regulatory requirements.
- Preliminary evaluation of technology.
- Feasibility study and preliminary risk assessment.
- Safety and security considerations.
- Nonfunctional requirements (e.g., development standards, program-naming convention standards).

Each requirement in the requirements specification must be "testable." A "testable" requirement includes an objective criterion and it is nonambiguous. A "testable" requirement provides the advantage that it can be recorded in quantified terms and allows for a subsequent review and independent evaluation of the test results.

Selection of Hardware Based on Capacity and Functionality

Based on the identification of operational functions and design, computer hardware technologies can be selected. Depending on available technology and cost, automated functions can be assign to the computer hardware or software. Computer hardware can be further decomposed into a number of subelements. Processor, memory, I/O and networks are some examples.

Process, field instruments, control requirements, available technology and cost are some of the factors driving the selection of the hardware. This selection is specified in the requirement specification and the implementation described in the design specification. The design specification needs to be sufficiently detailed in order to familiarize the implementation team (e.g. engineering) and the hardware vendor with the requirements and special considerations of the process, field instrument, and control requirements.

The requirements include, but are not limited to, the following:

- Purpose of the system.
- Regulatory requirements.
- Information and material inputs.
- Preliminary block diagrams.
- Data processing requirements (e.g., supervisory control and data acquisition).
- Number and type of I/O cards.
- Instrumentation and cabling.
- Control and information outputs.

Operating modes.
 Alarms and alerts.
 Safety features.
 Error checking.
 Reporting.
 Redundancy requirements.
 Environmental requirements.
 Network requirements.
 Supporting utilities requirements.
 Hardware/human machine interfaces.
 General plan and acceptance criteria.

The critical field instrumentation must support accuracy and reliability requirements over the entire process range conditions.

Inspection and Testing of the Operational Functions

Software engineering practices may include documented unit testing, code reviews, explicit high-level and low-level design documents, explicit requirements and functional specifications, structure charts and data flow diagrams, function-point analysis, defect and resolution tracking, configuration management, and a documented software development process.

These are the same quality principles that the FDA expects to be used during the development and maintenance of computer systems. These quality principles shall be contained in procedural controls. Inspections and testing are part of these principles.

Testing and inspections are activities performed as part of the development methodology. Numerous inspection steps are undertaken throughout the system development and operational life to determine whether a computer system is validated. These include static analyses such as document and code inspections, walk-through, and technical reviews. These activities and their outcomes help to reduce the amount of system-level functional testing needed in the operational environment in order to confirm that the software meets the requirements and intended uses.

Reproducibility of the Testing Results Based on Statistics

Testing is not just executing a program using a test data file or randomly selected test cases just prior to implementation. It is an on going process using techniques based on Statistical Process Control (SPC) principles and product quality concepts implemented as components of a Statistical Quality Control (SQC) program.^[6]

If software systems are viewed as a manufacturing facility that produces the desired output products, then statistical sampling procedures and statistical inference can be used to predict the reliability of test results. Instead of paying too much attention to the development of the application, another factor that requires attention is the data (raw material) to be converted into information (product). Information flow is a design technique that may be helpful in achieving this task.

Concerning testing, the input and output domains must be strictly defined. This suggests a response to the following: 1) What sampling technique will ensure an adequate subset of possible input values that will provide as complete a test of the software as possible? and 2) What information sampling procedures will allow the developers to determine product reliability?

It is suggested that White and Black box test cases design strategies be used to sample the data (input domain), including Equivalent Partitioning, Boundary Analysis and Error Guessing, Cause-Effect Graphing, and Structural Tableau.

The basics of Software Testing must be understood before the more abstract principles of statistical inference are tackled.

Documentation of the Validation Process

Design specification

System requirements are allocated to the software design. During the technical design it is described how each specification described in the system specification deliverable is to be implemented. This includes also developed subsystems components and interfaces, data structure, design constraints, algorithms and system decomposition. This activity is very critical to medical device companies. Design inputs are contained in the requirements of the computer system, and design output(s) can be included as part of the specification of the design.^[7] This design is the input for developing integration test and operational checks.

Design according to the development methodology and specific procedural controls.

Computer hardware and software architecture.

Data structures.

Flow of information.

Interfaces

Put together the design.

Perform design reviews. Verify whether the risks previously identified were mitigated as part of the solution presented in the design.

Finalized the test planning.

Design Part 11 technical controls.

Approve the design specification deliverable.
 Conduct in-process audit activities associated with the technical design.
 Re-visit the risk analysis.

Begin the planning of development of procedural controls for those Part 11 requirements not covered by technology.

Validation plan

Validation plans are documents that tailor a firm's overall philosophies, intentions, and approaches to be used for establishing performance adequacy to a specific project. They state who is responsible for performing development and validation activities. They identify which systems are subject to validation, define the nature and extent of inspection and testing expected to be done on each system, and outline the protocols to be followed to accomplish the validation.

In summary, validation plans describe the following:

- Organizational structure of the computerization project.
- Responsible departments and/or individuals.
- Resource availability.
- Risk management.
- Time restrictions.
- SLC and development methodology to be followed.
- Deliverable items.
- Overall acceptance criteria.
- Development schedule and timeline.
- System release sign-off process.
- Sample format for key documentation.

Test results and evaluation

Although installation qualification (IQ)/operational qualification (OQ)/PQ terminology has served its purpose well and is one of the many legitimate ways to organize computer system testing tasks in FDA-regulated industries, this terminology may not be well understood among many software professionals. However, organizations performing regulated operations must be aware of these differences in terminology as they ask for and provide information regarding computer systems.

Once the qualification protocols have been completed, test results and data need to be formally evaluated. Written evaluation needs to be presented clearly in a manner that can be readily understood. The report should also address any nonconformance or deviation to the validation plan encountered during the qualification and resolution. The outline of the report parallels the structure of the associated protocol. The qualification testing

should be linked with relevant specification's acceptance criteria, such as PQ vs. system requirements specification deliverable, OQ vs. system specification deliverable, and IQ vs. technical design specification deliverable. If applicable, it is included as part of the summary of the results of inspections and technical review of all technologies that are elements of the systems.

In very large validation efforts, a report references (by title and document reference number) other documents that satisfy the protocol requirements. In smaller validation efforts, actual evidence is incorporated as appendices to the report.

The documentation and results of the qualification efforts are assembled and reviewed by appropriate and qualified personnel. Following the review, the personnel responsible for the criticality of the system, including QA, approve the qualification effort.

The approval of all qualification reports is a confirmation that the computer system as a whole has been proven to fit its purpose and that all essential elements of documentation are available. On computer systems controlling manufacturing equipment (process control systems), the approval of all qualification reports indicates the release of the computerized systems to the Process/Product Performance Qualification. On other computer systems, the approval of all reports indicates the release of the system to the user.

Test results on Part 11 shall be addressed in the associated qualification report.

The Project Report summarizes the outcome of each activity performed to develop or maintain computer systems and the verification of critical checkpoints throughout the entire development process. The end-result is to verify that good quality development procedures were adhered to as established in the project plan.

All verification and testing results completed during the project shall be addressed in the Project Report as well.

The approval of the project report is the event to be considered prior to the release of the system for operation.

Validation maintenance

After the system has been released for operation, computer system maintenance activities take over. The maintenance activities must be governed by the same procedures followed during the Development Period.

The validated status of computer systems performing regulated operations is subject to threat of changes in its operating environment, either known or unknown. Adherence to security, operational management, business continuity, change management, periodic review, and decommissioning provides a high degree of assurance that the system is being maintained in a validated state. It is

the objective of organizations to have procedures in place to minimize the risk of computer systems performing regulated operations out of validated state.

Maintenance in computer systems becomes an essential issue, particularly when a new version of the supplier-provided standard software is updated. A change control procedure must be implemented whereby changes in the software and computer hardware may be evaluated, approved, and installed.

If necessary, additional analysis may be needed to evaluate the changes (e.g., impact analysis) to the computer systems. The procedure should allow for both planned and emergency changes to the system. This procedure must include provision for updating of pertinent documentation on the system, including procedures. Records of changes to the system must be kept for the same period as any other regular production document.

Table 1^[8] summarizes the periods and events applicable to the operational life of computer systems and associated key practices.

Evaluation of Modification to Computer Systems

As required by regulations, all maintenance work must be performed after the evaluation and approval of the work and must be consistent with the selected SLC methodology. Maintenance to a software system includes, among other things, the following:

- Perfective maintenance or correcting the system because of new requirements and/or functions.
- Adaptive maintenance or correcting the system because of a new environment, which could include new hardware, new sensors or controlled devices, new operating systems, new regulations.
- Corrective maintenance or correcting the system because of detection of errors in the design, logic, or programming of the system. It is essential to recognize that the longer a defect is present in the software before it is detected the more expensive it is to fix it.

Preventive maintenance or correcting the system to improve future maintainability or reliability in order to provide a better basis for future enhancements.

Change management procedural control is in place when the validated system is released for use. The change management procedural control provides for the following activities:

- Identifying and specifying the change.
- Assessing risk, criticality, and impact of change.
- Specifying testing requirements and acceptance criteria.
- Implementing change after authorization.
- Performing regression testing.
- Reviewing of change(s) with an independent reviewer.
- Updating system and user documentation to reflect implemented change(s).
- Establishing of provisions for the management of “emergency change,” including expeditious documentation modifications.

SYSTEM DEVELOPMENT FILES

One key element to support the SLC is the availability and maintenance of system development files. The developer shall document the development of each system unit, system component, and configuration items in software development files.

The developer should establish a separate system development file for each unit or a logically related group of units. The developer should document and implement procedures for establishing and maintaining system development files. The developer should maintain the system development files until the retirement of the system. The system development files should be available to the agency review upon request. System development files may be generated, maintained, and controlled by automated means. To reduce duplication, system development files should not contain information provided in other documents or system development files. The set of system

Table 1 Period/events computer systems operational life

Period/event	Representative characteristics	Key practices
Early operational life	Phased roll outs	Problem reporting and maintenance
Maturity	Corrective, adaptive, perfective, and preventive maintenance	Operational audit Performance evaluation
Aging	Maintainability issues of obsolete technology (e.g., access to electronic records)	Periodic review Re-engineering analysis

development files shall include (directly or by reference) the following information:

Design considerations and constraints.
Design documentation and data.
Schedule and status information.
Test requirements and responsibilities.
Verification and test procedures, and results.

CONCLUSION

The validation of computer systems in the U.S. FDA-regulated environment is an ongoing process that is integrated with the entire System Life Cycle (SLC). Quality to a software system is introduced by following the system life cycle and following the key validation elements.

Dendrimers

Antony D'Emanuele

David Attwood

Ragheb Abu-Rmaileh

University of Manchester, Manchester, U.K.

INTRODUCTION

Dendrimers are highly branched macromolecules that can be subdivided into three architectural components: a central core branched cell, interior branch cells, and branch cells possessing surface groups. The term dendrimers was coined in the early 1980s by Tomalia et al.^[1] from the Greek words dendron (tree) and meros (part) and relates to the symmetrical branch-like structure of these polymers. Dendrimers are synthesized through a stepwise repetitive reaction sequence, which gives rise to different generations of the same molecule and determines the size and surface functionality of the macromolecule. The dendrimer microenvironment possesses some interesting properties. Cavities in the core structure and folding of the branches create cages and channels, which, depending upon how the dendrimer is constructed, may be either hydrophilic or hydrophobic in nature. Specific binding sites may also be incorporated. The surface groups of dendrimers are amenable to modification and can be tailored for specific applications. The dendrimer architecture, therefore, permits control over properties such as shape, size, density, polarity, reactivity, and solubility. The structure of a generation 3 polyamidoamine (PAMAM) dendrimer is shown in Fig. 1. Dendrimers can be very large; PAMAM dendrimers have been synthesized with a diameter in excess of 10 nm. Fig. 2 compares the size of a series of PAMAM dendrimers to a number of biological structures. Table 1 gives the relationship between generation and dendrimer size, molecular weight and number of surface groups.^[2] As can be seen, an increase in dendrimer generation results in a doubling in the number of surface groups.

Although the synthesis of dendrimer-like structures was initially described in 1978,^[3] it is only since the 1990s that there has been an intense interest in these polymers, partly attributable to the availability of a commercial source of PAMAM dendrimers.

SYNTHESIS

Dendrimers may be prepared by either a convergent^[4–6] or a divergent approach.^[1] Much of the work on dendrimers has been based on the commercially available Starburst® PAMAM dendrimers,^[1,7] which may be synthesized from

an ammonia or ethylenediamine core (EDA), and possess an amidoamine branching structure. This family of dendrimers was introduced by Tomalia et al. in 1985^[1] and are prepared by the divergent approach, where the branching dendritic structure is built up from a central core. PAMAM dendrimers are synthesized by an iterative process involving two reactions: Michael addition followed by amidation. The first iteration of these two reactions results in the formation of a zero-generation (G0) dendrimer, the subsequent addition–amidation cycles each result in growth and the formation of a higher generation (Fig. 3), this synthetic cycle yields a full-generation (amine terminated) dendrimer. Cessation of the reaction after the Michael addition results in the eventual formation of a half-generation (carboxyl terminated) dendrimer. The growth of a dendrimer is self-limiting, and governed by steric hindrance arising from the introduction of numerous surface groups.^[8,9] The convergent method of synthesis involves the initial creation of the dendrimer branches, followed by assembly to form the dendrimer. The convergent method produces a system with a low polydispersity, while the divergent method can produce dendritic structures with defects arising from incomplete reactions.^[10] However, the divergent method has the advantage of being able to yield higher generation dendrimers. The methods of synthesis and their relative merits have been reviewed by Dykes.^[11]

Three structural components are common to all dendrimers: a core unit, peripheral groups, and the multiple branching units that span the two. The core unit in dendrimers is usually an important part of the structure as it covalently links the dendritic “wedges” (dendrons). However, cored dendrimers have been synthesized in which surface crosslinking maintains the integrity of the dendritic structure.^[12]

The preparation of structurally perfect dendrimers traditionally can be time-consuming due to the required repetitive coupling and activation steps, and the necessity for extensive purification.^[13] PAMAM dendrimers are just one of several types of dendrimers with pharmaceutical applications that have been synthesized. Poly(aryl ether) dendrimers were developed by Hawker and Fréchet and were the basis of unimolecular micelles and cancer drug conjugates.^[4,14,15] Wang, Zeng, and Zimmerman^[16]

Fig. 1 Structure of a G3 PAMAM dendrimer. (From Ref. [110], © 2000 Elsevier Science.)

reported the synthesis of poly(phenylacetylene) and poly(benzyl ether) (PBE) dendrimers to encapsulate benzamidinium guests by hydrogen bonding. Jansen, de Brabander-van den Berg, and Meijer^[17] described the synthesis of poly(propyleneimine)-based dendrimers and their applications in the encapsulation of guest molecules. Numerous other dendrimer families have been synthesized with a wide range of applications.^[18–20]

Several peptide dendrimers have been reported,^[21–25] a major application of which is for the preparation of multiple antigen peptides (MAPs). For example, Tam^[26] used the poly(lysine) platform to prepare a MAP. These peptides are used to activate the immune system to produce large numbers of anti-peptide antibodies, and their

use avoids the immunogenicity and the other disadvantages associated with conventional antigenic systems.

Dendrimer structure is often confirmed with a variety of techniques, including ¹H- and ¹³C-NMR, mass spectrometry, size-exclusion chromatography, high performance liquid chromatography, electrophoresis, elemental analysis, and thermal analysis.^[14,27–35]

PHYSICOCHEMICAL PROPERTIES

Unlike classical polymers, dendrimers have a high degree of molecular uniformity, narrow molecular weight distribution, specific size and shape characteristics, and

Fig. 2 A dimensionally scaled comparison of a series of PAMAM dendrimers (NH_3 core) with a variety of proteins and bioassemblies. (From Ref. [7], © 2001 Elsevier Science.)

a highly functional terminal surface. The branching nature of the structure can lead to large 3-D globular structures, which at high molecular weights may approximate spheres. These structures are relatively fixed, in marked contrast to linear polymers that are random coils and,

depending on the solvent, may adopt a variety of configurations.

Many of the physical properties of dendrimers may be predicted, at least qualitatively, from molecular modeling of the growth process. With the PAMAM dendrimers,

Table 1 Physical characteristics of PAMAM dendrimers (EDA core)

Generation	Molecular weight	Measured diameter (nm)	Surface groups
0	517	1.5	4
1	1,430	2.2	8
2	3,256	2.9	16
3	6,909	3.6	32
4	14,215	4.5	64
5	28,826	5.4	128
6	58,048	6.7	256
7	116,493	8.1	512
8	233,383	9.7	1024
9	467,162	11.4	2048
10	934,720	13.5	4096

(From Ref. [2].)

Fig. 3 Synthesis of a PAMAM dendrimer: exhaustive Michael addition of amino groups with methyl acrylate, followed by amidation of the resulting esters with EDA. (From Ref. [7], © 2001 Elsevier Science.)

a fully developed dendrimer structure first appears only after dendrimer growth to at least G1.5, since it is not until the point that the dendrimer contains all three branch cell components, i.e., the core, interior, and surface branch cells. This transition from lightly branched structures to fully developed dendritic structure is referred to as the critical branching stage.^[36] Because of the progressive growth pattern, the dendrimers are constructed in a precise manner and a linear increase of the radii of the fully developed dendrimers with increase of generation is expected. However, because the surface cells amplify according to a geometric progression with increasing generation, it is clear that ideal growth cannot continue indefinitely and there will be a critical generation at which the reacting dendrimer surface will not have sufficient space to accommodate all of the required new units. This stage is referred to as the de Gennes dense-packed state and occurs around G7 in the PAMAM dendrimers.^[37] Dendritic growth beyond this point is of course possible but leads to products of imperfect structure because not all of the surface groups are able to participate in reaction due to steric effects. Such defective generations have been called “hairy dendrimers.”

Similar molecular modeling of the 3-D character of the polyether dendrimers, [37] on the other hand, shows that

steric crowding of the surface branches becomes prohibitively high on approaching G4. As a consequence, it is predicted that the polyether dendrimers will be denser with far fewer internal cavities than the PAMAM series. The PAMAM dendrimers have much higher internal surface area and solvent-filled volume than the polyether dendrimers. Within the PAMAM dendrimer spheres formed at $G > 4$, the solvent accessible surface increases with generations so that the fraction of the internal molecular surface increases from about 29% of the total solvent accessible surface at G4, to 69% for G5, and about 124% for G6.^[37] Thus, at G6 there is more internal surface area than external surface area. For polyether dendrimers on the other hand, the internal surface area reaches a maximum of approximately 20% for G3 and G4. The possibility of binding or entrapping small molecules in these cavities mimics the drug delivery attributes that are offered by liposomes.

Dendrimer Size and Shape

Computer-simulated modeling of the structures of the PAMAM dendrimers^[37–39] highlights changes in external appearance with increase in generation (Fig. 2), through a continuum of molecular shapes ranging from open

amorphous shape for the early generations (G0 to G3) to a more tangled spheroidal network for the fully developed structures at $G > 4$. These shape changes are a consequence of the tethered steric constraints imposed on the developing branches. In Fig. 4, these shape changes are expressed in terms of the aspect ratios of the corresponding longest and shortest principle moments. Experimental determination of the exact shape of dendrimers presents difficulties mainly because most of the commonly used techniques are at their limits of reliability in the size range involved.

Very few experimentally determined transmission electron microscope (TEM) images of dendrimers have been published in the literature, probably because their size range and their fragile organic composition make the resolution of such objects by electron beam techniques very difficult.^[40] Quality images of dendrimer molecules may provide insight into the actual uniformity, sphericity, and hollowness of the macromolecules. TEM studies on PAMAM dendrimers by Tomalia et al.^[1] showed highly monodisperse spheroids. For example, images of the sodium salt of G3.5 dendrimer showed that almost 90% of all particles had diameters ranging within 10% of the average value determined by computer simulations. Jackson et al.^[41,42] examined positively stained PAMAM dendrimers of G5 to G10 using this technique. The shapes of the stained molecules were shown to be spherical for G7 to G10 with some molecules showing "edges." For G5 and G6, the resolution of these molecules was less than with larger dendrimers because smaller molecules took up less amount of stain. The mean diameters of the dendrimers measured by TEM compared well with measurements made with small-angle x-ray scattering (SAXS).

Fig. 4 Comparison of the change in PAMAM dendrimer morphology (aspect ratio I_z/I_x) as a function of generation. (From Ref. [37], © 1990 Wiley-VCH.)

Dendritic structures have been studied on a variety of surfaces including glass,^[43] graphite,^[43,44] and charged solid surfaces^[45,46] using atomic force microscopy (AFM). In a recent study, Zhang et al.^[47] reported the topographical imaging of well-separated, individual polyphenylene dendrimer molecules and their aggregates on mica surfaces using noncontact AFM techniques. The observed height was in good agreement with the size of a single dendrimer molecule as calculated by molecular dynamics simulation. In addition, pulse force mode AFM was used to study the stiffness and adhesion properties of the individual dendrimer molecules to this surface and these were related to the molecular structure and the chemical nature of the outer surface of the dendrimers.

Experimental measurements of the hydrodynamic radius of PAMAM dendrimers with ammonia or EDA cores by size exclusion chromatography and viscometry^[37,39] have shown the expected linear increase of hydrodynamic radius with generation beyond G3. The values were intermediate between the calculated theoretical maximum values that would result from maximum extension of all branches, and the minimum value allowed by acceptable packing of the atomic mass units around the initiator core. The expanded dendrimer would be expected to occur with more ideal solvents; the compressed form would be more likely in theta solvents. A small-angle neutron scattering (SANS) study of the effect of solvent quality on the molecular dimensions of G5 and G8 PAMAM dendrimers^[48,49] showed a decrease of the radius of gyration of the dendrimers by approximately 10% with decreasing solvent quality. The same studies showed that the dimensions of these two dendrimers were constant to within 5% over the temperature range -10 to 50°C .

PAMAM dendrimers have been obtained as very monodisperse samples by careful removal by ultrafiltration of propagating agents and any bridged forms. Measurement by a variety of techniques, notably size exclusion chromatography and low-angle laser light scattering,^[37] SANS and SAXS,^[50,51] and intrinsic viscosity measurement^[39] have shown polydispersity indices for PAMAM dendrimers in the range 1.01–1.08, indicative of a relatively monodisperse distribution of dendrimer sizes in solution. A similar monodispersity of size was noted from SAXS measurements^[52] on dilute methanolic solutions of G3 to G10 PAMAM dendrimers and poly(propyleneimine) dendrimers made with primary amines built around a diaminobutane core (DAB-dendr- $(\text{NH}_2)_x$, $x = 16, 32$, and 64). In contrast, dilute solutions of polyol hyperbranched polymers exhibited scattering indicative of the inherent irregularity of internal segment densities and of overall size, giving more polydisperse solutions. SANS measurements on poly(propyleneimine) dendrimers terminated by primary

amines, DAB-*dendr*-(PA)₃₂ and DAB-*dendr*-(PA)₆₄, in methanol over a wide concentration range (dendrimer mass fraction between 0.01 and 0.80) have been reported by Topp et al.^[53] At concentrations at which the swollen dendrimer volume fraction was below 0.64 (the critical volume fraction for close packing of hard spheres), which corresponds to a dendrimer weight fraction of 0.25, the dendrimers in solution behaved as a dispersion of uniform soft spheres with no significant interpenetration between the segments of different dendrimers. At higher concentrations, however, the dendrimers “collapsed,” their size decreasing with increase of number density so that the volume fraction of the solution was maintained at approximately 0.64.

Surface Properties of Dendrimers

The surface properties of dendrimers are specific to the functional terminal groups that make up the surface of the dendrimers, which can be either reactive or passive moieties or even a combination of both. The type and number of functional groups and their ionization characteristics may affect dendrimer solution properties in various ways, e.g., by changing the solubility, potential for aggregation, and inter-dendrimer charge interaction. A dendrimer surface may contain multiple copies of a particular functional group and so would be an ideal molecule for substrate binding. Under conditions where the functional groups are ionized, the dendrimer becomes a macromolecular polyelectrolyte and as such it will interact strongly with oppositely charged particles. Polyelectrolyte dendrimers have been shown to adsorb strongly at various interfaces such as alumina/water and silica/water as well as associating with proteins or DNA.^[54–57]

Although dendrimers possessing a wide variety of functional groups have been synthesized, the most studied are those with amine or carboxyl groups. A titration curve of a 2% aqueous solution of a G4 PAMAM dendrimer against 0.2 M HCl^[58] shows two distinct inflection points that are indicative of the titratable terminal primary amines (pK_a 10.7) and the interior amines (pK_a 6.5). The titration characteristics have been confirmed by observation of ¹³C chemical shifts.^[1] The surface potential of the G4 PAMAM dendrimer calculated from titration curves is 63 mV.^[58]

Charge Interactions and Aggregation

A pronounced influence of pH and added electrolyte on the charge interactions between dendrimers with ionizable groups is expected in aqueous solution. Briber et al.^[50] investigated the intermolecular interactions between PAMAM dendrimers in concentrated solutions using

SANS and SAXS techniques. They showed that the molecules develop large scale interactions which can be screened by the addition of excess acid or electrolyte. SANS studies of the structural properties of poly(propyleneimine) dendrimers (DAB-*dendr*-(NH₂)₆₄) in D₂O examined the influence of the degree of ionization and solvent pH.^[59,60] Upon addition of HCl, the dendrimers become charged and the scattering patterns exhibited a single correlation peak indicating a spatial arrangement of the molecules due to the electrostatic repulsion. In the uncharged state, these dendrimers behave as “soft” molecules, i.e., they have a very high degree of flexibility with possible interpenetration at high concentration. In conditions where they are charged, however, the electrostatic forces cause a stretching of the branches and reduce their flexibility, i.e., they behave as “hard” particles.

Changes in the G6 PAMAM structure upon pH titration were studied using a polarity-responsive probe by Chen, Tomalia, and Thomas.^[61] Two possible models were proposed to explain the dendrimer behavior; in the first, some inward folding of the dendritic termini is presumed to occur at all basic pHs, resulting in a slightly less polar interior. At high pH (ca. pH 10) any protonation will occur on the more polar surface amines; as the pH is lowered to pH 8.3, the less polar amines will protonate and the average environmental polarity decreases, as was observed from the experimental measurements. Finally, further decrease of pH causes protonation of the internal amines and molecular expansion due to charge repulsion. In the alternative model, increasing protonation of dendritic termini is able to overcome entropy, forcing charged termini to the periphery; the resulting surface crowding results in the observed lower average environmental polarity. In this model, the polarity increase on decreasing pH below 8.3 arises from protonation of the amines that are located in the less dense, more polar dendritic interior. The first model is considered a denser core model of the G6 dendrimer, while the second is a denser shell model.

A detailed study of the physicochemical properties of G5 PAMAM dendrimers in aqueous solution by Nourse, Millar, and Minton^[35] revealed contrasting properties of amino-surface (G5-NH₂) and hydroxyl-surface (G5-OH) dendrimers. The hydrodynamic properties of G5-OH in dilute solution could be described by a model in which the solute was represented by a single species of quasi-spherical particle having a molar mass equal to the theoretically predicted molar mass of the dendrimer and a hydrodynamic radius of about 3.1 nm. In contrast, size exclusion chromatography and sedimentation equilibrium ultracentrifugation studies on G5-NH₂ have indicated the formation of oligomeric aggregates in aqueous solution even in the presence of high salt concentration. Measurement of the concentration dependence of

sedimentation of G5-OH in pH 7.2 phosphate buffer indicated the presence of significant electrostatic repulsion overlaid on weakly attractive interactions leading to the formation of nonspecific aggregates at sufficiently high dendrimer concentration.

Static and dynamic light scattering studies by Milhem^[58] have shown that G4 PAMAM dendrimers do not exhibit intermolecular aggregation in aqueous solution at concentrations up to 7% w/w at pH 10.5, or even when fully unionized at pH 14.

Internal Structure

Many of the potential applications of dendrimers depend directly on the organization and distribution of internal segment densities and the possibility of reduced density at the core. The first theoretical treatment of internal structure of the amine-terminated PAMAM dendrimers by de Gennes and Hervet^[8] predicted a segment distribution function that has the highest density on the periphery and a relatively hollow core. On the other hand, Monte Carlo simulations by Lescanec and Muthukumar^[62] predict that the highest density is at the center with a decaying profile to the edge of the molecule. Both the models have shortcomings; the de Gennes model does not account for backfolding, which could be an incorrect assumption for flexible dendrimers, whereas the Lescanec and Muthukumar model is based on kinetically grown rather than equilibrium structures. The predictions of these models have been tested against the experimental data from a variety of techniques.

The SAXS studies on methanolic solutions of G3 to 10 PAMAM dendrimers by Prosa et al.^[52] indicate that lower generation dendrimers are less dense than their higher generation relatives, but after the first few generations the average density appears to be roughly independent of generation and uniform throughout the structure with no indication of any sizeable minimum in density near the dendrimer core (with the G10 dendrimer) contrary to the predictions of the de Gennes model.

Measurements of molecular density^[39] and intrinsic viscosity^[37,39] of PAMAM dendrimers indicate an unusual variation with dendrimer generation. Minimum density and maximum intrinsic viscosity were observed at around G4, which suggests that the fully developed dendrimers have a high accessible internal surface area in a solvent-filled intramolecular free volume that may consist of internal cavities and channels. Similar findings were reported by Mourey et al.^[63] for PBE monodendrons (based on dihydroxybenzyl alcohol) and tridendrons produced by coupling these dendrons to a trifunctional core, 1,1,1-tris(4'-hydroxyphenyl)ethane prepared by the convergent method. A maximum intrinsic viscosity occurred at G3 for tridendrons and G5 for monodendrons,

consistent with the model developed by Lescanec and Muthukumar that predicts inward folding of branch units, a maximum density in the center, and a distribution of terminal groups throughout the structure. If there are no specific interactions between the groups and if the branch units of the dendrimer are flexible enough to allow some gradual backfolding, then it is reasonable that the equilibrium structure has maximum density in the center because this corresponds to maximum entropy for the molecule and also provides relief of steric crowding of terminal groups. It is also significant that this model describes the behavior of both PAMAM and polyether dendrimers implying that it may be of general application to all flexible dendrimers.

A study of the molecular characteristics in dilute solution (D_2O , 1%) of the first five generations of the poly(propyleneimine) dendrimers DAB-*dendr*-(NH_2)_x and DAB-*dendr*-(CN)_x, ($x = 4, 8, 16, 32$, and 64) by Scherrenberg et al.^[64] has suggested some degree of backfolding of molecules within the dendrimer. Comparison with molecular dynamics calculations indicated that the poly(propyleneimine) dendrimers could be regarded as flexible molecules with a relatively homogeneous density distribution, not in line with either the de Gennes or Lescanec and Muthukumar models.

There is considerable evidence from a variety of techniques for a dendrimer model composed of a relatively soft or spongy interior surrounded by a considerably harder outer molecular surface, the so-called "dendritic box."^[17] ¹³C-NMR measurements of spin lattice relaxation times of specifically tagged PAMAM dendrimers^[65–68] have shown considerably reduced mobility in the outer surface groups relative to the interior segments. Meltzer et al.^[65,66] performed ¹³C-NMR relaxation studies on hydroxyl terminated PAMAM dendrimers, in order to understand the influence of the end groups on the chain dynamics of the molecule (G0.5 to G10.5). The spin relaxation times (T_1) for each terminal carbon decreased continuously with an increase in generation, suggesting that segmental motion was increasingly restricted at the surface of the higher generations. Thus, it was concluded that the iterative branching process that creates the PAMAM architecture must at some point lead to severe steric crowding either at the molecular surface or throughout the volume of the molecule, as indeed is indicated from modeling of dendrimer growth. It was, however, noted that the mobility of the terminal groups on the surface of dendrimer molecules was higher than expected for the available area. Therefore, either the number of terminal groups must be much less than expected, possibly due to growth failure, or the conformation must be such that all the terminal groups do not reside at the surface due to their folding back into the interior of the molecule. Gorman et al.^[69] also showed

that some terminal groups (approximately 3) of a G3 dendrimer were located very close to the dendrimer core. An average of 25 of the 32 terminal groups were found on the geometric periphery which were more mobile than the others found elsewhere in the dendrimer molecule.

Differential scanning calorimetric (DSC) measurements on a variety of dendrimers including PAMAM dendrimers with NH_3 and EDA cores,^[39] and PBEs and phenolic-terminated polyesters^[27] have shown exponentially increasing glass transition temperatures with increasing molecular weight reaching an asymptotic value generally at about G3 or G4. These results show that a pronounced segmental mobility is retained within the internal volume, possibly around the core and over the first two or three generations in support of the conclusions from ^{13}C -NMR relaxation studies. Moreover, at about the fifth branch layer around the core, segmental motions responsible for the glass transition apparently reach their limiting values and cannot be extended any further.

Flow Properties and Inter-dendrimer Interaction

The flow properties of solutions of dendrimers have relevance not only for their possible use in pharmaceutical formulation, but also because of the insight that might be gained on the nature of any intermolecular interactions between dendrimers. It might be expected from computer modeling of the dendrimer shape that lower generations, which have an open "plate-like" or "dome-like" entity, would readily permit a branch from a neighboring dendrimer to penetrate into the interior. This tendency would be further enhanced by intermolecular hydrogen bonds between the interior amide groups of two interpenetrating molecules or between the primary amine units of one molecule and the amide carbonyl oxygens of another. In contrast, the closure of the dendrimer outer surface at higher generations should result in minimal inter-dendrimer interactions.

Measurements by Uppuluri et al.^[36] using a cone and plate rotational rheometer on the first seven generations of EDA-core PAMAM dendrimers in medium and highly concentrated solution (30%–75% in EDA) showed typical Newtonian flow behavior over the entire range of shear stress and strain examined. An absence of any abrupt change in the slope of log zero-shear viscosity against log weight average molecular weight relationship was indicative of a lack of any significant interpenetration of dendrimers to form quasi-networks even at such high concentration where any such inter-dendrimer interaction would be accentuated. Similar measurements on neat linear polyamidoamine illustrated the unique bulk flow properties of the dendrimers compared with a chain polymer of comparable molecular weight, which showed

an inflection in these plots associated with the onset of chain entanglement. There is also a fundamental difference in the flow properties of these dendrimers and colloidal suspensions of spheroidal particles, which typically show shear thinning properties above some critical shear rate, molecular weight, or concentration originating from a tendency of individual particles to aggregate. The viscosities of the dendrimer solutions were at least an order of magnitude lower than those usually found for similar solutions of chain-type macromolecules of comparable molecular weights and concentrations, i.e., they flowed much more easily than their chain-type equivalents. It was proposed that the atypical flow properties of the dendrimers compared to other high molecular weight synthetic polymers were a consequence of the unique dendrimer architecture, which above the critical generation results in globular spheroids whose outer surfaces close upon themselves or at least become dense enough to be impenetrable for other dendrimers or large molecules, giving rise to the Newtonian flow properties of these solutions. The situation is thus the reverse of that of typical long-chain polymers, where the probability of entanglement increases with increase of chain length. A pronounced sensitivity of solution viscosity to temperature and a stability of the dendrimer solutions to repeated loading, observed by these workers, suggested surprising flexibility of the dendrimer interior, in agreement with their reported ability to expand^[70] or shrink^[71] depending on solvent quality, solution concentrations, and temperature. These observations support a model of the dendrimer having a soft or spongy interior and a surrounding denser more congested shell.

A detailed rheological examination of the first eight generations of PAMAM dendrimers^[72] explored rheological behavior in the bulk (rather than solution) state under conditions of steady shear, shear creep, and dynamic oscillatory shear over a wide temperature range. A distinct change from single relaxation mode to a multirelaxation mode, Maxwell-type behavior at G4 was consistent with the soft interior-dense shell model involving the closure of the dendrimer molecular surface upon itself. Furthermore, an analysis of the free volume of PAMAM dendrimers revealed a dependence on generation that was consistent with the qualitative conformational change at G4 predicted by this model.

Further insight into the nature of the dendrimer surface has been provided by measurements of the melt viscosity of PBE monodendrons and tridendrons.^[73] Logarithmic plots of melt viscosity against molecular weight were linear with a slope close to the expected value of unity and no detectable inflection attributable to onset of chain entanglement. These observations confirm that the melt viscosity behavior is not dominated by chain entanglements and is fully consistent with a globular highly

branched structure with an increasingly congested surface lacking intermolecular chain entanglements.

PHARMACEUTICAL APPLICATIONS OF DENDRIMERS

Encapsulation/Solubilization of Drugs by Dendrimers

The concept of encapsulating guest molecules into a special, egg shell-like structure was proposed by Maciejewski in 1982.^[74] There has been a considerable interest in the use of dendrimers to encapsulate or interact with labile or poorly soluble drugs in order to protect the drug and enhance bioavailability. Such guest–host dendrimer systems have also been proposed as controlled delivery systems. Although several terms have been applied to systems in which drugs have been encapsulated within a dendritic structure, these systems are usually only distinguishable by subtle differences in dendrimer architecture. The interaction within the dendrimer may

be simple physical entrapment, or can be more specific involving hydrophobic interactions or hydrogen bonding.

Dendritic structures having a hydrophobic core and hydrophilic surface layer have been described as unimolecular micelles.^[14,15,75–79] However, unlike conventional micelles, the dendritic structure is independent of dendrimer concentration; thus, they do not possess a critical micelle concentration. Newkome et al. described a monomolecular micelle cascade polymer based on a neopentyl core and 36 carboxylic acid surface groups.^[77] A number of lipophilic probes (e.g., phenol blue) were found to be associated within the lipophilic infrastructure of the micellanoates whose size ranged 3 nm–5 nm in diameter. Hawker et al. described the convergent synthesis of dendritic polyether unimolecular micelles based on an 3,5-dihydroxybenzyl alcohol building block with carboxylate surface groups.^[14] The dendritic micelles were capable of specific nonbonding interactions (π – π interactions in this case) through tailor-made molecular inclusion sites. The electron-rich macromolecular structures (Fig. 5) were able to solubilize a variety of polycyclic aromatic compounds in water. The solubilizing power of

Fig. 5 Water soluble unimolecular dendritic polyether micelle. (From Ref. [14], © 1993 Royal Society of Chemistry.)

the dendrimer was found to increase with dendrimer concentration and also as the electron density of the polycyclic aromatic compounds increased. Hybrid dendritic structures were also described in which hydrophobic and hydrophilic chain ends were segregated at distinct ends of the globular structure, thus allowing for preferential orientation at certain interfaces. Dendrimers based on 3,5-dihydroxybenzyl alcohol have limited solubilization capacity as a result of small internal cavities within the dendrimer. Liu et al. synthesized water-soluble dendritic unimolecular micelles based on 4,4-bis(4'-hydroxyphenyl)pentanol building blocks and a surface shell of polyethylene glycol (PEG) chains.^[15,32] The building block was chosen in order to increase the flexibility and cavity size of the dendritic structure while the PEG was chosen because of its good water solubility and demonstrated biocompatibility (Fig. 6). The solubilization capacity of the unimolecular micelle was demonstrated by the solubilization of pyrene (~365-fold increase in solubility) in aqueous solution and entrapment of a model drug (indomethacin) at a loading of 11% w/w

(G3 micelle), a value that corresponds to approximately nine drug molecules per micelle. The drug-loaded dendrimer provided sustained release of indomethacin over a period of 30 hr.

Jansen et al. describe the entrapment of molecules in a dendritic box,^[17,80–82] based on poly(propyleneimine) dendrimers with a chiral shell of protected amino acids (Fig. 7). The resulting dendritic structure, 5 nm in size, possesses a dense shell (as a result of bulky surface groups) with solid-phase character. Guest molecules were entrapped within the internal cavities of the dendrimer. The dense outer shell prevents diffusion from the dendritic box, even after solvent extraction, prolonged heating, or sonication. The entrapment effect was only seen with higher generation structures, e.g., a dendrimer with 64 amine end groups entrapped up to four Bengal Rose molecules. An extension of this work involved the shape-selective liberation of guests from dendritic boxes.^[81] Hydrolysis of the surface t-BOC groups (with formic acid) of a dendritic box containing entrapped Bengal Rose and 4-nitrobenzoic acid resulted in perforation of the dendrimer

Fig. 6 G2 dendritic unimolecular micelle. (From Ref. [15], © 2000 Elsevier Science.)

Fig. 7 Dendritic box based on poly(propyleneimine) dendrimer. (From Ref. [81], © 1995 American Chemical Society.)

allowing the release of 4-nitrobenzoic acid but not of Bengal Rose. The larger Bengal Rose molecule could only be liberated following hydrolysis of the outer shell by 12 M HCl under reflux for 2 hr.

An approach to increase the loading of guest molecules within a dendritic structure involves the creation of additional void space by removal of the dendrimer core, producing the so-called cored dendrimers.^[12,83] This approach obviously requires a means of maintaining the structural integrity of a cored dendrimer and thus the connections among the dendritic wedges. The approach taken by Zimmerman's group was to extensively cross-link the dendrimer surface groups by a ring-closing metathesis reaction prior to removal of the core (Fig. 8). Core removal was via three cleavable ester bonds, with the remaining structure being unaffected as a consequence of robust ether linkages. Cored dendrimers have been compared to hollow polymeric nanospheres with the potential to encapsulate substances. It is not clear, however, how guest molecules could be loaded into such structures.

A recent report focusing on the encapsulation of drugs referred to two types of possible systems, such as

the Dendrilock[®] and Dendripore[®] type structures.^[84] The Dendrilock structure is based on a dendrimer with a congested outer shell, the release of guest molecules from which was either immeasurably slow or nonexistent. In contrast, Dendripores are lower generation dendritic host structures with less compact surfaces allowing time dependent release of guest molecules. The proposed mechanism of release is similar to that reported by Meijer's group,^[17,80–82] i.e., dendrimer surface density is used as a means of controlling the release of guest molecules.

Kojima et al. synthesized G3 and G4 PAMAM dendrimers with PEG grafts and examined their ability to encapsulate the hydrophobic drugs adriamycin and methotrexate.^[85] The modified PAMAM dendrimers were reported to have PEG grafted to every surface group and were estimated to have a hydrodynamic diameter of up to 14.7 nm. The purpose of the grafts was to improve biocompatibility and modify biodistribution. It was found that drug loading increased with dendrimer size and increasing chain length of PEG grafts, and up to 6.5 adriamycin or 26 methotrexate molecules could be

Fig. 8 Synthesis of a cored dendrimer. (From Ref. [12], © 1999 American Chemical Society.)

incorporated into a dendrimer. While there was evidence of the sustained release of methotrexate from a dendrimer carrier in an aqueous solution of low ionic strength, no control could be achieved in isotonic solutions.

Although the number of guest molecules incorporated into a dendrimer may be dependent to a limited extent on the architecture of a dendrimer, the loading capacity may be dramatically increased by the formation of a complex with the large number of groups on the dendrimer surface. The interaction between charged dendrimers and oppositely charged polyelectrolytes may result in the formation of soluble complexes.^[86–91] Studies on the interaction of poorly soluble drugs have shown that solubility may be dramatically enhanced in the presence of dendrimer.^[92–95] The solubility of ibuprofen, for example, was increased by a factor of over 140-fold in the presence of a 2% w/v PAMAM G4 dendrimer solution, over twice that achieved using a micellar solution of 2% w/v sodium dodecyl sulfate. The dendrimer–drug complexes were thought to involve an electrostatic interaction between the carboxyl group of the ibuprofen molecule and the amine groups on the dendrimer surface, though recent studies indicate the additional involvement of internal amine groups.^[58] Although enhancing solubility, complexes formed as a result of electrostatic interactions may not provide sufficient control over drug release.^[93] In order to provide a more controlled release of drugs, covalent conjugates have been synthesized between drugs and the numerous surface groups on a dendrimer. The hydrophobic drug ibuprofen was coupled onto the surface of G4 PAMAM dendrimers.^[58,96,97] It was found that insoluble complexes were formed when more than five ibuprofen molecules were attached to the dendrimer surface. However, much higher drug loadings (up to 32 ibuprofen molecules per dendrimer) could be achieved when PEG chains were attached to the dendrimer. The release of ibuprofen from these dendrimer conjugates was examined. Liu et al. characterized a number of conjugates based on polyether dendrimers and a number of model drugs (cholesterol and two amino acid derivatives).^[32] The solubility of the conjugates was maintained by grafting short PEG chains onto the dendrimer surface. Zhuo et al. synthesized a series of dendrimers with a branch structure similar to PAMAM dendrimers, but with a cyclic core of 1,4,7,10-tetraazacyclododecane.^[34] The resultant dendrimer had four branches emanating from the core. 5-fluorouracil (SFU), conjugated onto the surface of the dendrimers, could be released by hydrolysis of the resulting conjugate.

Uptake of Dendrimers

A polymeric drug carrier such as a dendrimer must traverse through various cell barriers, i.e., epithelial and endothelial cells, before reaching its target. Transepithelial

transport is an important factor when considering movement across the intestinal cell wall, while transendothelial transport is relevant to the movement of carriers across the vasculature to reach their target cells/receptors. Generally, transport across biological barriers is determined by factors pertaining to both the nature of the carrier (e.g., drug molecule, macromolecule, and particle) and the nature of the biological barrier. Important carrier attributes are molecular weight, charge, hydrophobicity, flexibility, and the geometry of the molecule. Biological barrier attributes include the barrier's location and function; the blood-brain barrier is, for example, less permeable to molecules than the intestinal epithelium.

Proposed mechanisms of uptake of structures of dendritic size from the gastrointestinal tract include persorption, endocytosis by enterocytes, paracellular transport, uptake by intestinal macrophages and uptake through the gut-associated lymphoid tissue.^[98] Wiwattanapatapee et al.^[99] investigated the potential of 3 nm–7 nm diameter anionic and cationic PAMAM dendrimers to transverse an everted rat intestinal system. It was found that the uptake of PAMAM dendrimers was most likely to occur across enterocytes by transcytosis. It was also reported that cationic (full generation) PAMAM dendrimers are retained in the tissue. This retention could be a consequence of adsorption of positively charged dendrimers (as well as other polycations) onto negatively charged cell membranes, an effect also reported by Katchalsky.^[100] Anionic PAMAMs were found to have high serosal transfer rates with potential as an oral drug delivery system.

Florence and coworkers studied the uptake, after oral administration, of a G4 poly(lysine) dendrimer (diameter = 5 nm) modified with a lipid surface.^[98,101] In vivo studies indicated that there was a rapid uptake of dendrimers from the gastrointestinal tract, demonstrating their potential as particulate delivery systems. It was found that uptake of the dendrimers was not uniform along the gastrointestinal tract; there was preferential uptake through lymphoid tissue in the small intestine, but no uptake in lymphoid tissue in the large intestine. Peyer's patches in the small intestine preferentially absorb dendrimers over enterocytes, whereas the opposite is true in the large intestine. The level of uptake of the dendrimers was lower than that exhibited by polystyrene particles in the size range 50 nm–3000 nm. It was suggested that there was an optimum size for nanoparticulate uptake by the gut and that a reduction in size did not necessarily correlate with an increase in uptake.

Tajarobi et al.^[102] studied the transport of a series of full generation PAMAM dendrimers (G0 to G4) across Madin-Darby canine kidney (MDCK) cells. It was found that the permeability of dendrimer across these cells was in the order $G4 \gg G1 > G0 > G3 > G2$ and was governed

by the balance between the size of the dendrimer and its interaction with the cells. One of the factors attributing to the high permeability of the G4 dendrimer was the fact that it compromised cell integrity. Zhang and Smith^[103] also showed that higher generation PAMAM dendrimers may disrupt or influence the integrity of the cells.

The factors influencing the extravasation of PAMAM dendrimers across microvascular network endothelium was reported by El-Sayed et al.^[104] It was concluded that the rate of transport is dependent on size and molecular weight, as well as physicochemical properties such as geometry and charge. An increase in size of PAMAM dendrimers resulted in a corresponding exponential increase in extravasation time. Cationic dendrimers interact with the negative cell walls, and their extravasation time is therefore increased. The balance between charge and geometry was illustrated by the fact that at physiological pH, the polycationic PAMAM dendrimers exhibit faster extravasation than neutral PEG molecules of the same radius.

A certain degree of caution is required in the interpretation of uptake data where dendrimers are conjugated to a label. As reported by Yoo and Juliano, a dendrimer labeled with a fluorescent dye (Oregon Green 488) was a much better delivery agent for antisense compounds than unmodified dendrimer.^[105] It is also important to fully characterize dendrimers as there is a concern regarding polydispersity, particularly with higher generation dendrimers.^[103,104]

Delivery of DNA and Oligonucleotides by Dendrimers

Dendrimers have emerged as efficient carriers of DNA for the transfection of cells.^[29,106–115] A study by Haensler and Szoka^[106] demonstrated the high efficiency transfection of a variety of suspension and adherent cultured mammalian cells using plasmid-PAMAM dendrimer complexes. A maximal value of transfection was obtained by varying complex size and plasmid/dendrimer ratio. Expression was found to be unaffected by lysomotrophic agents and transfection efficiency was increased by over two orders of magnitude when a membrane-destabilizing peptide was attached to the dendrimer. The high transfection efficiency of dendrimers was believed to be related to dendrimer size, shape, and ability to buffer pH change in the endosomal compartment. The dendrimers were found to be well tolerated by cells and less toxic than poly(lysine). It is believed that polycations such as dendrimers act as a scaffold to condense DNA (the G6 dendrimer used in the study has a diameter similar to the histone core of chromatin, 7 nm). Efficient internalization is a result of the net positive charge of the DNA-polycation complex interacting with negatively charged cell-surface groups. Kukowska-Latallo et al.^[107] reported much higher levels of

transfection mediated by dendrimer compared to poly(lysine), and noted that different types of cell might be specifically transfected with different types of dendrimers depending on the cellular metabolism of the DNA–dendrimer complex. Lysomotropic agents were found to have a beneficial effect on transfection. The difference in levels of transfection achieved in the two studies was attributed to the possible presence of impurities in the commercial dendrimer preparations used in the earlier study by Haensler and Szoka. A subsequent study from the Szoka group^[29] reported that monodisperse PAMAM dendrimers in fact produce low levels of transfection whereas partially degraded dendrimers produced much higher levels of transfection (> 50-fold). The higher levels of transfection activity were attributed to the high molecular weight degraded component (fractured dendrimer) being less sterically constrained. The increased flexibility of the dendrimer branches enables the fractured dendrimer to be compact when complexed with DNA and to swell when released from DNA in cells. A comparison of the transfection efficiency of dendrimers to a range of polycationic gene transfer agents indicated that degraded dendrimers displayed high transfection activity with relatively low cytotoxicity.^[116] Polyethylene glycol conjugated low generation PAMAM dendrimers have been shown to be more efficient transfection agents than partially degraded (fractured) dendrimers.^[115] It is believed that the presence of PEG chains on PAMAM dendrimers would mimic some of the essential properties of fractured high generation dendrimers (enhanced flexibility of chains). The use of lower generation dendrimers and the addition of PEG chains also enhances biocompatibility.

Dendrimers have been successfully used as a delivery system for antisense oligonucleotides (ODNs).^[105,117–120] Hughes et al.^[117] reported the significant enhancement of the effectiveness of antisense ODNs in the presence of non-toxic concentrations of G5 PAMAM dendrimer. Bielinska et al.^[118] reported the enhanced activity of antisense ODNs and antisense cDNA plasmids in the presence of PAMAM dendrimers in an *in vitro* cell culture system. Dendrimer was believed to enhance the transfer of ODN into cells. The electrostatic binding of the phosphodiester ODNs to dendrimers also extended their intracellular survival. Dendrimers at concentrations required to be effective ODN carriers were reported to be noncytotoxic.

Cancer Therapy Based on a Dendritic Platform

A number of studies have examined the use of a dendrimer drug carrier to treat a variety of tumors. One approach has been based on the exploitation of the enhanced permeability and retention effect (EPR effect) to localize drug conjugates in tumor tissue.^[121] A second approach

has involved the conjugation of a drug-loaded dendrimer to a targeting moiety such as an antibody or a receptor-specific molecule (ligand) to target specific tumor cells. Structurally, dendrimers are multibranched and can therefore carry a relatively large payload of drug, as well as other bioactive macromolecules on their surfaces or interior. They are also monodisperse systems and the size of conjugates may be calculated with relative accuracy.

Cisplatin is an important anticancer agent, but as with other platinate drugs it suffers from low water solubility, severe toxic side effects, and the inherent or acquired resistance seen in a number of tumors. Malik et al. conjugated a G3.5 PAMAM dendrimer with a carboxylate surface to cisplatin to produce a dendrimer–platinate that had a high drug loading (~ 25%), was highly soluble and released platinum slowly *in vitro*.^[122] *In vivo* studies demonstrated that intraperitoneal administered dendrimer–platinate and cisplatin were equally effective in mice bearing L1210 tumors, whereas only the dendrimer–platinate was active in mice bearing B16F10 tumors. When administered intravenously to treat a palpable subcutaneous melanoma, the dendrimer–platinate displayed antitumor activity, whereas the cisplatin was inactive. It was shown that the dendrimer–platinate selectively accumulated in solid tumor tissue by the EPR effect, and that the conjugate was also significantly less toxic than cisplatin.

Kono, Liu, and Fréchet^[123] reported the synthesis of polyether-based dendrimers conjugated to methotrexate or folate residues, which may be used to target the folate receptor that is overexpressed in almost all solid tumors. Wiener et al.^[124] also used folate-conjugated PAMAM dendrimers to target tumors, and showed that these dendrimers were accumulated in cells in a receptor specific manner.

Other examples exist of dendrimers (particularly PAMAM dendrimers) being conjugated to antibodies to target tumors. Barth et al.^[125] synthesized boronated PAMAM dendrimers conjugated to the IB16-6 monoclonal antibody, which is directed against the murine B16 melanoma. The conjugate was designed for boron neutron capture therapy. The immunoconjugates showed a high level of immunoreactivity *in vitro*, but *in vivo* were localized in the liver and spleen. The same group conjugated epidermal growth factor (EGF) onto a boronated G4 PAMAM dendrimer to target brain tumors.^[126] When administered intrathecally the conjugate was selectively delivered to EGF receptor positive gliomas, but when delivered intravenously the conjugates were once again localized in the liver and spleen, and very little crossed the blood–brain barrier. Abu-Rmaileh et al. proposed a drug loaded PAMAM based dendrimer conjugated to an antibody fragment specific to tumor cells bearing the carcinoembryonic antigen.^[127]

The conjugates had PEG chains grafted onto their surface to minimize uptake by the reticuloendothelial system. Kobayashi et al.^[128] demonstrated that monoclonal antibodies may be conjugated to dendrimers with minimal loss of immunoreactivity. There have also been a number of reports on the conjugation of dendrimers to antibodies for use in immunoassay.^[129,130]

Baker et al. discussed the technical requirements of a smart nano-device therapeutic to diagnose and treat cancer and proposed two approaches.^[131] The first involved the attachment of all the active moieties required for functionality to the same dendrimer, while the second involved the construction of a dendrimer cluster of many dendrimers each carrying a different functional group (Fig. 9). A G5-Folate-FITC conjugate was synthesized and used to successfully target cell lines expressing the folate receptor.

Biological Evaluation of Dendrimers

While several pharmaceutical applications for dendrimers have been proposed, there is limited evidence to suggest that they are safe for human use. This may be partly due to difficulties in assessing these materials. An ongoing concern in dendrimer science is sample purity, and it is not a simple procedure to unambiguously establish the purity of high-generation dendrimers.^[103,104] It is likely that new dendrimers will be developed from building blocks known to be biocompatible or degradable in vivo to natural metabolites, e.g., the poly(glycerol-succinic acid) dendrimers as described by Carnahan and Grinstaff.^[132] Information on dendrimer toxicity and biocompatibility has been included in a number of studies,^[99,102,106,107,115,117,125,126] but there are only two

reports that specifically address the safety of dendrimers. Roberts, Bhalgat, and Zera^[133] investigated G3, G5, and G7 PAMAM dendrimers. The dendrimers were tested in V79 cells and Swiss-Webster mice for a number of biological properties including toxicity, immunogenicity, and biodistribution. Biological complications were observed only with G7 dendrimers at high concentrations. The biodistribution of the dendrimers was generation dependent; G3 showed the highest accumulation in kidney tissue, whereas G5 and G7 preferentially localized in the pancreas. Although it was concluded that the dendrimers did not exhibit properties that would preclude their use in biological applications, it was stressed that the biodistribution of dendrimer preparations should be carefully evaluated. The authors also noted that the dendrimers were not pure (yield ranged 62.7%–76.7%). Malik et al.^[134,135] examined the biocompatibility of PAMAM, poly(propyleneimine) with either diaminobutane or diaminoethane as core, and poly(ethylene oxide) (PEO) grafted carbosilane (CSi-PEO) dendrimers. These dendrimers were used to systematically study the effect of dendrimer generation and surface functionality on biological properties in vitro. It was reported that dendrimers bearing amine surface groups showed concentration-dependent hemolysis, and changes in red cell morphology were observed. CSi-PEO dendrimers and those dendrimers with carboxylate terminal groups were neither hemolytic nor cytotoxic towards a panel of cell lines in vitro. In general, cationic dendrimers were found to be cytotoxic. Preliminary studies with polyether dendrimers showed that dendrimers with carboxylate and malonate surfaces were not hemolytic at 1 hr, but unlike anionic PAMAM dendrimers they were lytic after 24 hr. Cationic ¹²⁵I-labeled PAMAM

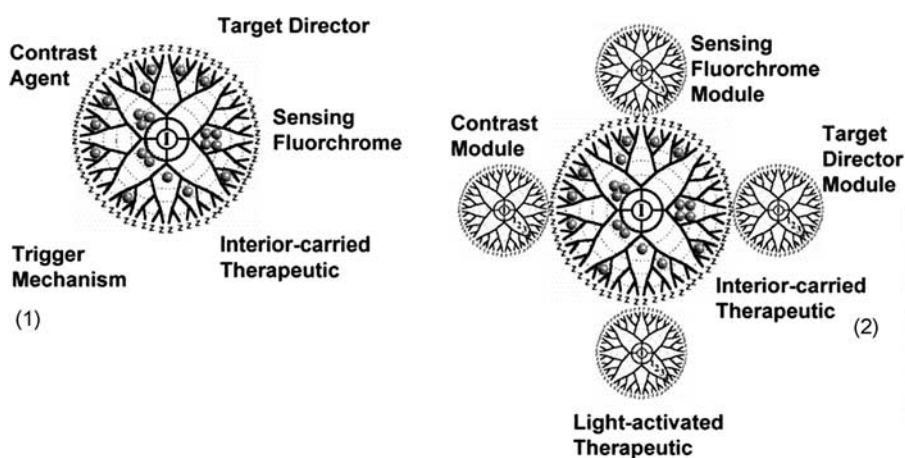

Fig. 9 Two alternative designs for a dendritic nanodevice cancer therapeutic. Configuration 1 is a therapeutic agent built around a single dendrimer molecule (70 Å in diameter). Configuration 2 is a cluster reagent where multiple dendrimers are clustered together, each providing a different functional unit (approx. 200 Å in diameter). The advantage to this latter approach is that functional units can be mixed and matched in a combinatorial method to address almost any type of cancer. (From Ref. [131], © 2001 Kluwer Academic Publishers.)

dendrimers (G3 and G4) administered i.v. to Wistar rats were cleared rapidly from the circulation. Anionic PAMAM dendrimers (G2.5, 3.5, and 5.5) showed longer circulation times with generation-dependent clearance rates. In general, lower generation dendrimers had longer circulation times. The inherent toxicity of the higher generation cationic dendrimers suggest they are unlikely to be suitable for parenteral administration, especially if they are to be used at a high dose. The results indicated that dendrimer structure must also be carefully tailored to avoid rapid hepatic uptake if targeting elsewhere is a primary objective. The study did not consider the issue of dendrimer purity. It is not clear whether the concentrations reported are clinically relevant. In both of the above studies, unmodified dendrimers were evaluated. However, the biological profile of a dendrimer-based delivery system (with surface modifiers and a payload of drug) is likely to be different. It has been shown that DNA-PAMAM dendrimer complexes are less mytotoxic than free dendrimer, possibly due to the fact that the complex reduces the overall positive charge of the dendrimer.^[136] The addition of PEG chains to PAMAM conjugates has been found to increase circulation times and modify biodistribution, with less conjugate being accumulated in the liver and kidney.^[137]

CONCLUSIONS

Dendrimers are a unique class of hyperbranched polymers with well-defined size, shape, and chemical functionality and with properties not found in classical linear and cross-linked polymers. There have been significant developments in the last decade in many areas of dendrimer research, partly due to the commercial availability of dendrimers such as PAMAM, but also the result of the synthesis of several novel dendritic structures. Numerous pharmaceutical applications have been proposed for these hyperbranched polymers, and given the rate of current developments, it is envisaged that dendrimer-based formulations will appear in the next decade.

CRYSTALLIZATION: SIGNIFICANCE IN PRODUCT DEVELOPMENT, PROCESSING, AND PERFORMANCE

Naír Rodríguez-Hornedo
Brent D. Sinclair

University of Michigan, Ann Arbor, Michigan, U.S.A.

INTRODUCTION

Understanding crystallization processes is important for the rational formulation, process development, and stability of pharmaceutical products. Whereas thermodynamics describes the equilibrium behavior of a system, pharmaceutical products most often encounter far-from-equilibrium conditions during processing, storage, or delivery. These conditions lead to the creation of metastable liquid or solid states. Metastable liquid states may include freeze concentrated solutions, solutions of weak acids or bases exposed to a pH change, solutions prepared by dissolution of salts of weak acids or bases, and solutions prepared by dissolution of a high energy form. Metastable solid states include amorphous solids, polymorphs, and solvates. Because crystallization provides a means to reduce the free energy of the system to the most stable state, crystallization mechanisms and kinetics determine the extent to which metastable states are reached and maintained.

Whereas knowledge of equilibrium phase diagrams is useful in identifying the concentration (or activity) and temperature regions of thermodynamic stability of solid phases, information on the crystallization kinetics is essential in determining solid phase outcomes. Nucleation and growth rates control the isolation of desired solid state modifications as well as the particle size distribution (number of particles, mean diameter, and standard deviation) and particle shape or morphology. The lack of information on crystallization processes leads to unwanted or previously unknown nucleation events that threaten the development of a pharmaceutical product. Dunitz and Bernstein (1) documented cases of “disappearing or elusive polymorphs,” which provide evidence for the consequences of poor process control in crystallization of polymorphic systems. The recent shortage in the supply of capsules of the HIV protease inhibitor Norvir (ritonavir), due to the sudden formation of a crystalline structure different from the one harvested for months (2), illustrates the decisive role that nucleation mechanisms and kinetics have on crystallization. Nichols and Frampton (3) have reported considerable efforts that failed to crystallize the

metastable polymorph of paracetamol as described in the initial publication of the crystal structure (4). The critical role of crystallization kinetics in determining the appearance of crystalline modifications is also recognized by the FDA and described in the guidelines for the manufacturing of drug substances (5): “Appropriate manufacturing and control procedures (including in-process testing when needed) should be established for the production of the desired solid-state form(s). It should be emphasized that the manufacturing process (or storage condition) is responsible for producing particular polymorphs or solvates; the control methods merely determine the outcome.”

The goal of this chapter is to describe ways in which crystal structure, morphology, and crystallization kinetics can be utilized to reproducibly maintain metastable states and control solid-state outcomes. Experimental methods that can be employed to investigate the factors that regulate crystallization from solution will be presented.

CRYSTALLIZATION

A crystalline phase is created as a consequence of molecular aggregation processes in solution. These prenucleation clusters may achieve a certain size for a sufficient time to enable growth into macroscopic crystals. The rate and mechanisms by which crystals form in liquid solutions are determined by numerous factors, including:

- Solubility or solubility product (solubility product is important in solutions of nonstoichiometric composition)
- Supersaturation: concentration of crystallizing solute or ions that participate in crystallization
- Diffusivity or viscosity
- Temperature
- pH
- Solvent
- Soluble additives and impurities
- Reactivity of surfaces toward nucleation
- Volume of solution

- Rate at which supersaturation is created: cooling rate, freezing rate, rate of pH change.

The effect of these factors on crystallization processes is thoroughly explained in various books (6–10).

Questions on the transferability of crystallization microtechniques to larger scale processes that are reproducible require careful consideration and study of crystallization kinetics. Whereas operationally useful variables that describe crystallization methods are often related to crystallization outcomes, this approach lacks meaningful information for developing a process that yields reliable outcomes because the factors that determine the crystallization kinetics and outcomes are not explicitly considered. For instance, compare the following two approaches to describe the processes for the selective crystallization of polymorphs: (1) form I obtained by cooling; form II obtained by evaporation; and (2) form I obtained at a supersaturation x , temperature y , and time z at which crystals were harvested after crystallization onset; form II obtained at supersaturation x' , etc. Whereas the former approach is at best anecdotal, the latter employs the causative factors and leads to relationships between the crystallization kinetic parameters and the outcomes.

Control of the processes of nucleation and crystal growth is possible as long as the required information is available. In a study of crystallization of polymorphs of paracetamol by Nichols and Frampton (3), seeding with crystals of the desired solid phase and the time of harvesting the solid phase were found to have a significant effect on the isolation of the desired polymorph. The orthorhombic polymorph (metastable) could not be obtained by a previously reported method (4) “—slow evaporation from ethanol.” Dunitz and Bernstein (1) have explained the mystery of disappearing polymorphs by considering various examples and the relevant questions that were left unanswered. They state that, “Once a particular polymorph has been obtained, it is always possible to obtain it again; it is only a matter of finding the right experimental conditions.”

SUPERSATURATION

A solid phase is precipitated from solution if the chemical potential of the solid phase is less than that of the dissolved component. A solution in which the chemical potential of the solute is the same as that of the corresponding solid phase is in equilibrium with the solid phase under the given conditions (temperature, pH, and concentration) and called a saturated solution. In order for crystallization to occur, however, this equilibrium concentration or

solubility must be exceeded. This excess concentration or chemical potential is called supersaturation. Supersaturated states may be created by:

1. Methods that regulate the solute activity or activity product (concentration) include:
 - a. solvent removal (evaporation or freezing);
 - b. addition of indifferent salts with ions that participate in precipitation (addition of NaCl to sodium phosphate solution causing the precipitation of Na_2HPO_4); and
 - c. dissolution of a metastable solid phase (transformations of amorphous to crystalline, anhydrous to hydrate, more soluble to less soluble polymorph, and salt to free acid or free base).
2. Methods that regulate the solute solubility include:
 - a. temperature change;
 - b. pH change; and
 - c. addition of solvent or additives that lower the solubility of the solute.

Knowledge of the driving force for crystallization is essential, not only to characterize the kinetics but also to relate the crystallization outcomes to the parameters that regulate crystallization. The number of molecules required to achieve an effective nucleating cluster is inversely proportional to the supersaturation. Therefore, as the supersaturation is increased the probability of nucleation increases. However, nucleation is energetically more demanding than crystal growth, and there are supersaturation regions in which crystal growth proceeds while spontaneous nucleation is suppressed (metastable zone; 6,7,9).

The driving force for nucleation and growth is the difference in chemical potential of the solute in a supersaturated solution, μ_1 , and in a saturated solution, μ_{eq} :

$$\Delta\mu = (\mu_1 - \mu_{eq}) \quad (1)$$

Because $\mu = \mu^\circ + RT \ln a$, then

$$\Delta\mu = RT \ln (a/a_{eq}) = RT \ln (\gamma_1 c_1 / \gamma_{eq} c_{eq}) \quad (2)$$

and the supersaturation is

$$\sigma = \Delta\mu / RT = \ln (a/a_{eq}) = \ln (\gamma_1 c_1 / \gamma_{eq} c_{eq}) \quad (3)$$

If the activity coefficient, γ , is independent of concentration in the given concentration regime, then $\gamma_1 = \gamma_{eq}$, and the supersaturation becomes

$$\sigma = \ln (c/c_{eq}) = \ln (c/s) \quad (4)$$

where c is the concentration of the crystallizing substance in the supersaturated solution and s is the solubility. (This

notation is adopted to avoid the use of subscripts.) For c/s values smaller than 1.15

$$\sigma = \ln(c/s) \approx (c-s)/s. \quad (5)$$

Frequently used expressions for supersaturation are $[(c-s)/s]$ and the ratio (c/s) . If the supersaturation is attained by changing the pH, then the ratio of the concentration of the solution to the solubility at the given pH is the supersaturation ratio. Fig. 1 illustrates an example of the effect that changing the pH can have on the supersaturation of a weakly basic drug ($pK_a = 5.25$). When the pH of the solution is increased along the path represented by line ABC, spontaneous crystallization will occur when the pH corresponding to point C is achieved. When this boundary is exceeded (i.e., pH increased past point C), the rate of nucleation rapidly increases and the crystallization process may become less controlled. The concentration in the solution decreases as nuclei form and grow until the equilibrium concentration at the final pH is reached at point D. If the concentration is maintained at a pH somewhere in between points B and C, the solution is in the metastable region—where the probability of spontaneous nucleation is negligible while crystal growth on seeds occurs.

NUCLEATION

Nucleation is often the decisive step in the crystallization process and is of practical importance in pharmaceutical systems. Crystallization may occur intentionally or unintentionally during pharmaceutical processes in which

supersaturated conditions are achieved. Pharmaceutical processes in which supersaturated states are attained due to solvent removal include: freezing, freeze drying, spray drying, and drying of wet granulations. Other processes achieve supersaturation by changing solubility, during isolation of solid state forms, or during dissolution of weak bases in an environment in which pH is changing, such as in the gastrointestinal tract, as previously described.

The concentration threshold at which crystallization is observed at times shorter than the processing time or desired product shelf-life or GI transit time, is determined by the kinetic stability of supersaturated states and is regulated by the nucleation mechanisms and kinetics. Nucleation phenomena are equally important in the control of micromeritic properties and in the selective crystallization of a particular polymorph.

The crystallization-induced pH changes that occur during the freezing of sodium phosphate buffers illustrate the importance of kinetic events in determining final pH and product stability. The pH changes of sodium phosphate buffers during freezing at close-to-equilibrium conditions have been thoroughly studied (11, 12), and the phase diagram—phases, composition, and pH—of sodium phosphate buffers during freezing is shown in Fig. 2. However, it is recognized that during freeze-drying, freezing does not take place close-to-equilibrium and that large undercoolings and supersaturations are often encountered (13–16). During cooling of hypoeutectic solutions of monosodium and disodium phosphate, ice crystallization increases the total salt concentration, and the ratio of the dissolved salts will change when precipitation of

Fig. 1 Regions of varying thermodynamic stability for solutions of a weak base as a function of pH.

Fig. 2 pH and ratio of mono- to disodium phosphate salts during equilibrium freezing of sodium phosphate buffers, at initial buffer concentration of 20 mM. (Based on Ref. 11.)

Fig. 3 Comparison of pH during equilibrium and far-from-equilibrium freezing of sodium phosphate buffers. Equilibrium freezing, initial buffer concentration 20 mM, (—). Far-from-equilibrium freezing: Initial buffer concentrations of 100 mM (---) and 8 mM (- - -). (From Refs. 11 and 17).

one of the salts occurs. Disodium phosphate dodecahydrate is the least soluble salt in this system (eutectic temperature = -0.5°C and eutectic concentration = 0.11 M). Under close-to-equilibrium freezing, it precipitates first at initial pH values greater than 3.6, and at temperatures above the ternary eutectic of -9.9°C . This corresponds with the ternary eutectic composition at monosodium to disodium phosphate molar ratios of 3.42:0.06. Because precipitation of $\text{Na}_2\text{HPO}_4 \cdot 12\text{H}_2\text{O}$ consumes HPO_4^{2-} ions, the pH of the unfrozen solution decreases to the equilibrium value of 3.6.

If one wishes to design a formulation to be freeze-dried in which the active product ingredient has a narrow pH range for optimal stability, at what initial pH and buffer concentration should the formulation be prepared before freezing so that the pH remains within the specified range during freezing? In other words, does selective salt crystallization occur at the freeze concentrations achieved during the freeze-drying process, and what is the concentration dependence of salt crystallization in such systems? Based on thermodynamic considerations, sodium phosphate buffer solutions are expected to reach a buffer concentration of 3.5 M and a pH of 3.6 upon freezing to -10°C , if crystallization of ice and $\text{Na}_2\text{HPO}_4 \cdot 12\text{H}_2\text{O}$ proceed to equilibrium. This may be the case in seeded systems under slow cooling rates in which the pH and composition of the residual solution follow very closely the phase diagram (Fig. 3) (11). In contrast to the equilibrium behavior, studies during far-from-equilibrium freezing of sodium phosphate buffers show that the more dilute buffer solutions (lower concentrations of precipitating ions) experience greater departures from equilibrium and maintain pH values as high as 3 units above the equilibrium pH values (17). Thus, crystallization-induced pH changes are determined by the factors that regulate salt crystallization kinetics and depend on the initial salt concentration (pH and concentration).

Whereas buffer salt concentrations are not directly measured during freezing, they can be calculated from in situ pH measurements. Temperature–pH time profiles during freezing reveal the onset of ice crystallization

Fig. 4 Effect of initial buffer concentration on pH during far-from-equilibrium freezing of sodium phosphate buffer solutions. Initial pH of 7.4 at 25°C and initial buffer concentration of 100 mM and 8 mM. Solution temperature (—), bath temperature (---), and (—) pH. (From Ref. 17.)

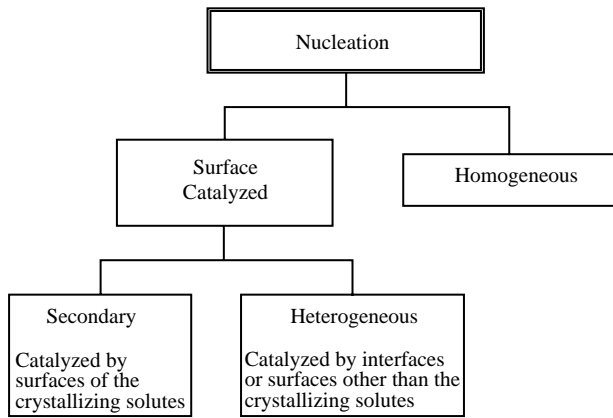

Fig. 5 Mechanisms for crystal nucleation.

(increase in temperature) followed by $\text{Na}_2\text{HPO}_4 \cdot 12\text{H}_2\text{O}$ crystallization (decrease in pH) in sodium phosphate buffer solutions of initial pH 7.4 and initial concentration in the range of 8–100 mM (Fig. 4) (17). This salt precipitates very early in the freezing process and within 15 min. after the onset of ice crystallization.

Nucleation Mechanisms

Nucleation mechanisms can be divided into two main categories: homogeneous and surface- or interface-catalyzed (7–9,18), as shown in Fig. 5. Homogeneous nucleation rarely occurs in large volumes (greater than 100 μl) because solutions contain random impurities that may induce nucleation (19, 20). This type of nucleation is referred to as heterogeneous. A surface or an interface of different composition than the crystallizing solute may serve as a nucleation substrate by decreasing the energy barrier for the formation of a nuclei that can grow into a mature crystal. Nucleation that is promoted by crystals of the crystallizing solute is known as secondary nucleation. These mechanisms are thoroughly discussed by Mullin (7), Myerson (9), and Zettlemoyer (18).

Homogeneous Nucleation

Thermodynamic considerations for nucleation are based on the work of Gibbs (21), Volmer (22), and others, where the free energy change for an aggregate undergoing a phase transition ΔG is given by

$$\Delta G = \Delta G_V + \Delta G_S \quad (6)$$

where ΔG_S is the surface free energy change associated with the formation of the aggregate (a positive quantity),

and ΔG_V is the volume free energy change associated with the phase transition (a negative quantity). For homogeneous or heterogeneous nucleation

$$\Delta G_V = -\alpha l^3 \nu k_B T \ln \left(\frac{c}{s} \right) \quad (7)$$

where α is the volume-shape factor, l is the characteristic length, ν is the molecular volume of the crystallizing solute, k_B is Boltzmann's constant, and T is temperature. For homogeneous nucleation

$$\Delta G_S = \beta l^2 \gamma_{12}, \quad (8)$$

where β is the area shape factor and γ is the interfacial energy per unit area between the crystallization medium, 1, and the nucleating cluster, 2. Consequently, the overall free energy change for nucleation is decreased by a large supersaturation ratio (c/s) and by a low interfacial energy.

The factors that regulate nucleation are best appreciated by considering the equation for the rate of homogeneous nucleation from solutions:

$$\begin{aligned} J &= N_o \nu \exp \left(\frac{-\Delta G^*}{k_B T} \right) \\ &= N_o \nu \exp \left(\frac{-4\beta^3 \nu^2 \gamma_{12}^3}{27\alpha^2 (k_B T)^3 (\ln(cs))^2} \right) \end{aligned} \quad (9)$$

J is the number of nuclei formed per unit time per unit volume, N_o is the number of molecules of the crystallizing phase in a unit volume, ν is the frequency of atomic or molecular transport at the nucleus–liquid interface, and ΔG^* is the maximum in the Gibbs free energy change for the formation of clusters at a certain critical size, l^* . The nucleation rate was initially derived for condensation in vapors (23), where the pre-exponential factor is related to the gas kinetic collision frequency. In the case of nucleation from condensed phases, the frequency factor is related to the diffusion process (24). The value of l^* can be obtained by minimizing the free energy function with respect to the characteristic length:

$$l^* = \frac{2\beta \nu \gamma_{12}}{3\alpha k_B T \ln \left(\frac{c}{s} \right)} \quad (10)$$

For spherical clusters, $\alpha = 4\pi/3$ and $\beta = 4\pi$, based on the radius of the cluster. Therefore,

$$r^* = \frac{2\nu \gamma_{12}}{k_B T \ln \left(\frac{c}{s} \right)} \quad (11)$$

Considering these geometric factors, the rate for homogeneous nucleation of spherical clusters is

$$J = N_o \nu \exp \left(\frac{-16\pi v^2 \gamma_1^3 2}{3(k_B T)^3 (\ln(\frac{C}{S}))^2} \right) \quad (12)$$

Whereas the classical theory of nucleation is limited by the implicit assumptions in its derivation (described in detail in Ref. 6), it successfully predicts the nucleation behavior of a system (7–9, 18, 25). Inspection of the aforementioned equation clearly suggests that the nucleation rate can be experimentally controlled by the following parameters: molecular or ionic transport, viscosity, supersaturation, solubility, solid–liquid interfacial tension, and temperature.

Nucleation kinetics are experimentally determined from measurements of nucleation rates, induction times, and metastability zone widths (the supersaturation or undercooling necessary for spontaneous nucleation) as a function of initial supersaturation (6–8, 26). The nucleation rate will increase by increasing the supersaturation while all other variables are constant. However, at constant supersaturation, the nucleation rate will increase with increasing solubility. Solubility affects the pre-exponential factor and the probability of intermolecular collisions. Furthermore, when changes in solvent or solution composition lead to increases in solubility, the interfacial energy decreases because the affinity between crystallizing medium and crystal increases (6). Consequently, the supersaturation required for spontaneous nucleation decreases with increasing solubility (27), as shown in Fig. 6.

Fig. 6 Dependence of the critical supersaturation for nucleation on solubility of nitrofurantoin in (a) formic acid, (b) formic acid: water (4:1), (c) formic acid: ethanol (2:1), (d) formic acid: dioxane (2:1), (e) formic acid: methanol (2:1), (f) formic acid: water (2:1). (From Ref. 27.)

The dependence of nucleation rate on solubility is also consistent with Ostwald's law of stages (28) regarding the preferential formation of a metastable solid phase. It states the following: "When leaving an unstable state, a system does not seek out the most stable state, rather the nearest metastable state which can be reached with loss of free energy." This indicates that if the unstable solid state modification (the system with highest solubility) precipitates before more thermodynamically stable solid phases, it must have higher nucleation and growth rates than solid states of lower solubility. However, Ostwald's law of stages is not universally valid because the appearance and evolution of solid phases are determined by the kinetics of nucleation and growth under the specific experimental conditions (29–31).

Accounts of nucleation inhibition in the pharmaceutical literature are sometimes confusing because the dependence of the nucleation event (nucleation rate, metastability zone width, or induction time) on supersaturation is not considered. In search of additives that inhibit nucleation, induction times are often measured as a function of additive concentration, whereas the dependence of the nucleation event on supersaturation is neglected. Results from such studies possibly lead to the erroneous conclusion that the additive inhibited nucleation (32, 33) when, indeed, the additive decreased the supersaturation and frequently led to an undersaturated state. Hence, the system is under thermodynamic control instead of kinetic control.

An important factor contributing to the nucleation mechanism and kinetics is the volume of solution in which nucleation occurs. The dispersal of a bulk liquid into a collection of small droplets has been shown to be an effective way of achieving large supersaturations or undercoolings (19, 20). Precipitation and solidification in small volumes (droplets) involving emulsions have been used to study homogeneous nucleation processes (34) and for the control of purity, particle size, and morphology (35, 36). Dispersing a solution into small volumes isolates heterogeneous nucleants within a fraction of the drops and makes nucleation more difficult. Consequently, larger supersaturations need to be reached for nucleation to occur. The boundaries of possible outcomes are represented by the following scenarios: (1) crystals of very small size (even in the nanometer range) are formed as a result of the high nucleation rates (35, 36), or (2) a glass or amorphous solid is formed due to the low diffusion rates of molecules that inhibit the evolution of clusters to crystals within the time scale of the experiment (37).

Nucleation outcomes from solutions with initially the same composition may vary as a consequence of impurities, rates at which supersaturation was created, thermal histories, experimental techniques employed to detect

Table 1 Disodium phosphate crystallization behavior during far-from-equilibrium freezing of buffer solutions

Observation	$C_{\text{Na}_2\text{HPO}_4}^a$ (mM)	Reference
Crystallization begins to decrease	≤ 200	Murase and Franks (16, 38)
Does not crystallize	≤ 10	
Crystallization begins to decrease	≤ 15	Gómez (17)
Crystallization readily occurs	≥ 0.3	
Crystallization is not inhibited by $C_{\text{NaH}_2\text{PO}_4}^b \leq 94$ mM	6	
Readily crystallizes	190	Cavatur and
Crystallization inhibited by $C_{\text{NaH}_2\text{PO}_4} \geq 730$ mM	190	Suryanarayanan (39)

^a $C_{\text{Na}_2\text{HPO}_4}$ = initial disodium phosphate concentration in solution at 25°C.

^b $C_{\text{NaH}_2\text{PO}_4}$ = initial monosodium phosphate concentration in solution at 25°C.

precipitation, and solution volumes in which nucleation occurred. This is illustrated by comparing results of the selective crystallization of buffer components during freezing from various laboratories (16, 17, 38–39). The initial salt concentrations and the crystallization behavior of disodium phosphate during freezing of sodium phosphate buffer solutions are shown in Table 1. Murase et al. (16, 38) report that disodium phosphate precipitation occurs at higher initial buffer and disodium phosphate concentrations, compared to those observed in our laboratory (17). Murase et al. report that salt precipitation begins to decrease at initial buffer concentrations below 500 mM, corresponding to 200 mM disodium phosphate, compared with results from our studies where decreases in salt precipitation were detected at initial buffer concentrations below 8 mM, corresponding to 0.3 mM disodium phosphate. Furthermore, disodium phosphate did not precipitate at initial disodium salt concentrations below 10 mM, whereas our studies show that precipitation occurs at salt concentrations as low as 0.3 mM. Inspection of the experimental conditions under which these studies were done (Table 2) shows a trend towards lower extent of crystallization (and slower crystallization rates) with decreasing volume of solutions from 25 ml to 3 μ l and increasing rates of cooling to lower temperatures.

Neglecting the factors that regulate nucleation leads to misleading generalizations when developing guidelines to control precipitation by the addition of noncrystallizing additives. Consider, for example, the conflicting interpretation of additive effects on nucleation when these are expressed in terms of concentration ratios (additive to crystallizing solute) while ignoring other parameters. Data in Table 1 indicates that disodium phosphate precipitation is inhibited at $(\text{H}_2\text{PO}_4^-/\text{HPO}_4^{2-}) \leq 4$ (0.73 M/0.19 M) (39) whereas it is not inhibited at $\text{H}_2\text{PO}_4^-/\text{HPO}_4^{2-} \geq 16$ (0.094 M/0.006M) (17). Compared to the systems we studied, the buffers studied by Cavatur and Suryanarayanan (39) have much higher concentrations of monosodium phosphate (which increases the viscosity of solutions) in addition to smaller solution volumes and faster rates of cooling to lower temperatures. All of these factors contribute to delaying precipitation.

The effect of the viscosity of the crystallization medium on the nucleation rate has been described by Turnbull and Fisher (24). The frequency of atomic or molecular transport at the nucleus-liquid interface, ν , can be related to the bulk viscosity, η , with the Stokes–Einstein relation:

$$\nu \approx \frac{kT}{3\pi a_o^3 \eta(T)} \quad (13)$$

Table 2 Experimental conditions and methods of measuring progress of sodium phosphate crystallization during freezing

Reference	Volume of solution (μ l)	Cooling rate (°C/min)	Temperature (°C)	Method
Murase and Franks (16, 38)	2–5	0.62	–52	DSC, SEM
Gómez (17)	25×10^3	0.3–0.5	–10	pH

^a Personal communication.

where a_o is the mean effective diameter of the diffusing species. If the viscosity dependence on temperature is described by Arrhenius behavior, then

$$J = \frac{K}{\eta_o} \exp\left(\frac{-\Delta G^* - \Delta G_a}{kT}\right) \quad (14)$$

where ΔG_a is the activation energy for transport across the nucleus–liquid interface. Thus, the nucleation rate may go through a maximum when an increase in undercooling or supersaturation is accompanied by an increase in viscosity. This behavior has been observed in the nucleation of citric acid in aqueous solutions (40) and the crystallization of ice (41).

Heterogeneous Nucleation

Heterogeneous nucleation processes are of fundamental and practical importance in pharmaceutical systems because unintentionally or intentionally added surfaces or interfaces may promote nucleation. The reactivity of crystal surfaces as heterogeneous nucleants has significant consequences in the isolation of the desired solid-state modification and in the control of conversions between these modifications, because the free energy required for the formation of $2 = D$ nuclei is lowered by the presence of an appropriate substrate. Quantitatively, this is described by the following equation (42, 43):

$$\Delta G_s = \gamma_{12}A_{12} + (\gamma_{23} - \gamma_{13})A_{23} \quad (15)$$

where γ is the interaction energy per area, A is the surface area of the interfaces, and the subscript 3 represents the substrate. The total change in surface free energy will be lowered by favorable surface interactions between the aggregate and the substrate and unfavorable interactions between the crystallization medium and the substrate, due to the negative value of the second term in Equation (15). Consequently, increasing the surface area of the substrate will enhance nucleation.

The effectiveness of crystal seeding in controlling crystallization outcomes relies on the potential of crystal surfaces to promote heterogeneous or secondary nucleation (7, 8) while avoiding heterogeneous nucleation mediated by unknown contaminants. A review by Ward (44) on the structure, properties, and reactivity of organic crystal surfaces is recommended to develop strategies for the choice of surfaces that promote nucleation. Various studies (45–49) have demonstrated the influence of substrate topography, lattice parameters, crystallographic symmetry, and intermolecular interactions on surface-directed nucleation.

Heterogeneous nucleation mechanisms can significantly affect dissolution of metastable solid phases

because this form of nucleation can occur at low driving forces. Whereas the choice of a metastable solid phase with a solubility higher than other crystalline modifications is motivated by the expectation of faster dissolution rates, achievement of faster dissolution rates and higher concentrations in solutions is jeopardized by surface-mediated nucleation. We have reported (47) that the surface of the metastable phase of theophylline promoted the nucleation of the stable monohydrate crystals. The observed oriented growth of monohydrate crystals on the anhydrous surface is consistent with a close lattice match between the **b** and **c** crystallographic axes (47). Other studies on the dissolution of metastable solids, such as anhydrous theophylline (50) and anhydrous carbamazepine (51–53), have shown that crystallization of the stable phase occurs during dissolution (Fig. 7). It is unfortunate that, in view of the important influence that nucleation mechanisms have on dissolution of metastable solid phases, very seldom are studies carried out to identify the potential of substrate-mediated nucleation by the metastable modification. The information gained from this

Fig. 7 Nucleation and growth of dihydrate carbamazepine on crystal faces of anhydrous monoclinic carbamazepine in aqueous solutions of sodium lauryl sulfate (17.3 mM, 0.5%), $C/S = 1.15$ at 25°C. (From Ref. 136.)

type of study can be used in the design of methods to regulate crystallization during dissolution as well as during isolation of the desired solid form.

Carter and Ward (43) have identified a surface-mediated nucleation mechanism that involves a geometric shape match between planes of a ledge site on the substrate and planes of prenucleation aggregates. They have applied these concepts to the directed nucleation of polymorphs (45, 48). This work provides us with the attractive possibility that “a library of organic seeds can be used to control polymorphism, or to search for unknown polymorphs” (44). Molecular interpretations based on this approach are experimentally more accessible than those based on solvent-selective polymorph crystallization.

Experimental and Computational Strategies

Whereas nucleation phenomena have their origin at the molecular level, they are often described in terms of macroscopic properties due to the scarcity of experimental techniques that allow for monitoring events at the molecular level. Nevertheless, information about molecular association processes in supersaturated systems obtained by laser Raman spectroscopy and laser light scattering has been used to identify prenucleation clusters and growth units under well-defined experimental conditions. Methods that measure cluster size distributions are more appropriate for studying crystallization of macromolecules (54–58) due to the large sizes of prenucleation clusters, whereas Raman and fluorescence spectroscopic techniques are capable of providing information about the solution structure or the species present in solution (59–63). The implications for crystallization pathways are examined by comparing the solution and crystal structures at a molecular level and by combining information obtained from macroscopic analysis with results from molecular simulations (64–74).

Gavezzotti (75–78) and Desiraju (79–81) have described crystal engineering strategies to understand the molecular aggregation processes involved in crystallization and to elucidate the supramolecular motifs in organic crystals. In this context, crystals are viewed as solid-state supermolecules assembled by intermolecular interactions, with the basic approach of establishing a relation between molecular interactions and supramolecular structure. Recent studies by Gavezzotti (78) show how molecular dynamics calculations allow for simulation of solvent and kinetic effects on molecular aggregation.

The supramolecular assembly process can be controlled so that the precursor nuclei in solution adopt a structure that resembles the structure of the desired crystalline

modification (78, 82, 83). This concept has been used in the design of nucleation inhibitors to prevent growth of the stable polymorph and enhance the growth of the metastable polymorph (29, 84, 85). Davey et al. (64) have explained the solvent-dependent polymorph appearance of sulfathiazole by analyzing the intermolecular interactions in the various polymorphic structures and comparing them with the supramolecular assemblies that could exist in the different solvents. In this case, however, the solvent-dependent selective crystallization of a polymorph was not correlated with solubility (64, 86).

CRYSTAL GROWTH

As stable nuclei (those larger than the critical cluster size) form, they grow into macroscopic crystals. This portion of the crystallization process is known as crystal growth. This process consists of several stages through which the growth units (i.e., the crystallographic basis that is “tacked onto” the space lattice to form the crystal structure) pass. These include: (1) transport of the growth unit from or through the bulk solution to an impingement site, which is not necessarily the final growth site, (2) adsorption of the growth unit at the impingement site, (3) diffusion of the growth units from the site of impingement to a growth site, and (4) incorporation into the lattice.

Desolvation of the growth unit may occur anywhere in steps 2–4, or the solvent may be adsorbed with the growth unit. Because any of these steps can be the rate-limiting step in the crystal growth process and they are dependent on conditions such as supersaturation, temperature, additives or solvent, and the hydrodynamics of the system, crystal growth is generally divided into two main mechanisms: volume-diffusion controlled or surface-integration controlled (Fig. 8) (6–9).

Crystal growth is volume-diffusion controlled when the diffusion of molecules from the bulk to the crystal surface is the rate-limiting step whereas growth is considered surface-integration controlled if the incorporation of a growth unit into the lattice is the slowest process. Many crystallization studies involving proteins, small organic electrolytes, and nonelectrolytes have reported growth controlled by surface-integration (71–73, 87–94). The roughness of the crystal surface determines whether growth occurs by the continuous (relatively rough surfaces) or the layer (relatively smooth surfaces) mechanism.

Crystal growth by the layer growth mechanism describes the formation of steps (i.e., layers) by two different mechanisms—2-D nucleation and screw dislocation. The model for 2-D nucleation was developed by

Fig. 8 Mechanisms for crystal growth.

Volmer (95) and Stranski (96). The screw dislocation model was first described by Burton, Cabrera, and Frank (BCF;97). The details of the derivations for these models have been summarized in a number of other references (7, 9, 98, 99).

Two-dimensional nucleation occurs when nuclei at the crystal surfaces act as sources of steps that allow for the further incorporation of growth units. In general, this mechanism accounts for the crystal growth observed at high supersaturations. The screw dislocation mechanism often accounts for growth at lower supersaturations. When the supersaturation is below the threshold for formation of 2-D nuclei, the presence of screw dislocations provides a source of steps for the addition of growth units in an infinite sequence of equidistant and parallel steps.

Experimental Strategies

Depending on the objectives and applications of growth rate measurements, the growth rate may be expressed as:

1. overall linear growth rate, which is the rate of change of the volume equivalent diameter with time;
2. linear growth rate of a face, which is the rate of displacement of a crystal face in a direction perpendicular to the face; and
3. velocity, height, and spacing of growth steps spreading across a crystal surface.

The linear growth rate of a face can be expressed in terms of the step velocity, step height, and step spacing. Techniques used for in situ measurement of crystal growth rates as a function of supersaturation include monitoring:

Fig. 9 Surfaces of human insulin crystals showing that steps arise by different mechanisms depending on supersaturation. (a) At low supersaturation, steps are created by screw dislocations, D. (b) At high supersaturations, $c/s > 10$, steps occur at the edges of islands as a consequence of 2-D nucleation. (From Ref. 136.)

1. the crystal population by methods that measure particle size and number (100, 101);
2. the growth rates of individual crystal faces by optical microscopy with the use of a flow cell system (73, 87–90); and
3. the development of surface topography at the molecular level by atomic force microscopy (AFM 89, 91–94) and interferometric microscopy (71, 72).

Although various mathematical models have been used to identify the growth mechanism by fitting various equations to the experimentally measured face-growth rate dependence on supersaturation, it may be difficult to discriminate between mechanisms (73, 89, 102). This approach is often combined with examination of the surface topography to confirm the growth mechanism, as shown for human insulin crystals in Fig. 9. Monitoring the development of surface topography and transport processes during crystal growth will reveal events that are not evident from monitoring growth rates with optical microscopy. For instance, interactions of growth units

and additives with different crystal planes exposed on a surface may be deduced from the shape of 2-D nuclei and the kinetic anisotropy of the growth steps along crystallographic directions. These techniques have been successfully applied for identifying the crystal growth mechanisms and kinetics of small molecules (71, 72, 89) and proteins (91–94, 103).

CRYSTAL MORPHOLOGY

Crystal growth is governed by both internal and external factors. Internal factors, such as the 3-D crystal structure and crystal defects, will determine the nature and strength of the intermolecular interactions between the crystal surface and the solution; whereas external factors, such as temperature, supersaturation, solvent, and the presence of impurities, will affect the type of interactions at the solid–liquid interface. The external shape or morphology of a crystal is a consequence of the relative growth rates of the faces, with the slowest growing faces impacting the crystal morphology to the largest extent. Examination of crystal morphology can reveal the molecular events occurring at the crystal face–liquid interfaces during growth. Consequently, even when morphology does not play a significant role in quality control, studying it is essential to understand the kinetics of crystallization (104).

Crystal Structure and Nomenclature

Crystals are comprised of the long-range, 3-D periodic order of atoms held together through intramolecular covalent and ionic bonds and intermolecular noncovalent bonds. It is this long-range order that differentiates a crystalline solid from a glassy or amorphous solid which only demonstrates periodic order over a short range of atoms. When a chemical entity exists in more than one crystalline state—polymorph or solvate—each of these forms will have a different arrangement of atoms in the 3-D structure. Consequently, in addition to different physical and chemical properties, each of these forms has a unique crystal structure.

Considering the crystal from a purely geometric view (i.e., ignoring the exact arrangement of atoms), each crystal can be described by the smallest repeating translational unit in three dimensions, known as the unit cell. A unit cell is a parallelepiped, which can itself be described by six geometric measurements, three axes (designated “a,” “b,” and “c”) and the angles between these axes (designated “α,” “β,” and “γ”), known as the lattice parameters. The relationship between the six lattice

Table 3 Crystal systems and lattice parameters

System	Relationship between lattice parameters
Cubic	$a = b = c$ $\alpha = \beta = \gamma = 90^\circ$
Tetragonal	$a = b \neq c$ $\alpha = \beta = \gamma = 90^\circ$
Orthorhombic	$a \neq b \neq c$ $\alpha = \beta = \gamma = 90^\circ$
Rhombohedral (or Trigonal)	$a = b = c$ $\alpha = \beta = \gamma \neq 90^\circ$
Hexagonal	$a = b \neq c$ $\alpha = \beta = 90^\circ, \gamma = 120^\circ$
Monoclinic	$a \neq b \neq c$ $\alpha = \gamma = 90^\circ, \beta \neq 90^\circ$
Triclinic	$a \neq b \neq c$ $\alpha \neq \beta \neq \gamma \neq 90^\circ$

parameters defines to which of the seven unique crystal systems a particular crystal belongs (Table 3). Whereas the crystal system describes the geometric arrangement of the unit cell, the space group describes the individual translational and symmetrical relationships of the actual atoms within the unit cell. The combination of the lattice parameters, crystal system, space group and, ultimately, the individual atomic coordinates defines each unique crystal structure that exists for a crystalline solid. An example of the unit cell (with lattice parameters) and atomic coordinates for an anhydrous polymorph of the drug carbamazepine is shown in Fig. 10. This polymorph belongs to the monoclinic crystal system and the $P2_1/n$ space group (105).

Fig. 10 Unit cell of anhydrous monoclinic carbamazepine. Lattice parameters are marked with “a,” “b,” “c,” “α,” “β,” and “γ.” (From Ref. 105.)

Table 4 Nomenclature for anhydrous carbamazepine polymorphs

	CBZ(AM)	CBZ(ATrg)	CBZ(ATrc)	Reference
Crystal system	Monoclinic	Trigonal	Triclinic	
T_{melt}	175–180°C	192–194°C	192–195°C	
Nomenclature	III		I	106–109
	I	II	III	110–112
	beta	alpha		113
	monoclinic	trigonal		114
			triclinic	115

The convention of Miller indices is used to describe the planes within a unit cell. Miller indices are defined as the reciprocals of the intercept which the plane makes with each of the three crystal axes. Each plane is denoted by three parameters “*h*,” “*k*,” and “*l*.” Planes that are parallel to a crystal axis are given the Miller index of 0, whereas planes formed in the negative direction are written with a bar over the number in the Miller index. The Miller index of a single specific plane is written within parentheses (*hkl*), whereas the Miller indices describing a whole family of faces are written with braces {*hkl*}. The faces that exist and define the crystal morphology are termed morphologically important and are commonly identified by the Miller indices of the planes represented by those faces.

The use of nomenclature indicative of the crystal structure would alleviate much of the confusion that exists in the literature when describing different polymorphs or solvates. Whereas it is often convenient to use terminology such as “Form I and Form II” or “ α -form versus β -form,” this can lead to confusion when different investigators use inconsistent or, in some cases, conflicting nomenclature to describe the same polymorphic forms. For instance, carbamazepine has been shown to exist in at least three anhydrous forms and two solvated forms (a dihydrate and an acetate). Overlapping or conflicting nomenclature has been used when describing the three anhydrous forms and has led to much confusion (Table 4) (106–115). As can be seen, nomenclature arising from crystallographic information (in this case, crystal system) would be more meaningful and less confusing than the commonly used terminology.

The Role of Crystal Morphology in Pharmaceutical Processes

Knowledge of crystal morphology and ways to control and predict the morphology of drugs and excipients could prove invaluable in processing and product development. In a review on solid-state properties of powders, York has

discussed how changes in crystal morphology can affect several formulation parameters, such as particle size distribution, powder flow, mixing (and agglomeration), dissolution, compression, and tablet hardness (116). Crystal morphology could also impact the rheology and filtration of suspensions. Additionally, certain crystal habits may lead to lack of dose uniformity or erratic drug delivery, as is the case with aerosols where particle size is critical for delivery (117–119). It should also be emphasized that the effect of crystal morphology does not impact the active ingredient solely. Because excipients often comprise much larger percentages of the formulation, the crystal morphology of each component may have profound effects on the characteristics previously described.

Often during processing or delivery of a formulation, supersaturated states are created, which may lead to the crystallization of drug or excipient. Consequently, the interactions between drugs and excipient (or excipient–excipient interaction) could have a tremendous impact on the morphology. In the strictest sense, the excipient is an impurity with respect to the active ingredient (or vice versa) and may result in changes in the crystal morphology that could adversely effect both processing and/or delivery.

The presence of additives (intentional) or impurities (unintentional) have long been known to have a significant impact on crystallization (both nucleation and growth; 7, 9). If an additive (or impurity) selectively adsorbs to a crystal face, the growth rates of those faces will be altered resulting in a change in crystal morphology. For example, interaction of sodium taurocholate (STC) with the {111} faces of carbamazepine dihydrate (CBZ(D)) decreases the growth rate along the needle axis and results in more prismatic crystals (Fig. 11) (53, 120). Photomicrographs demonstrating the effects of STC on CBZ(D) morphology are seen in Fig. 12. Lechuga-Ballesteros and Rodríguez-Hornedo have shown how the adsorption of hydrophobic L-amino acids can inhibit the growth rate of the {012} faces of L-alanine resulting in a change in crystal morphology (89, 90, 101, 121). The presence of structurally similar additives has also been shown to significantly change the crystal

Fig. 11 Two-dimensional representation of the effect of sodium taurocholate (STC) on the crystal morphology of dihydrate carbamazepine (CBZ(D)). STC interacts specifically with the {111} faces of CBZ(D), resulting in inhibition of the growth of those faces and changing the morphology from needles to prisms.

morphology of paracetamol (70). Recently, there has been much work exploiting the selective interaction of additives with crystal faces in order to “tailor” the crystal morphology to a more favorable habit (122).

Monitoring the changes in morphology by visual examination can be a powerful tool when troubleshooting formulation problems. The appearance of crystals with different morphology is indicative of changes in the processing conditions, such as in the degree of supersaturation, rate of heating or cooling, or the presence (or absence) of impurities. Changes in morphology could also be the first suggestion of the appearance of a new crystal form (polymorph or solvate). Characterization techniques, such as x-ray powder diffraction, thermal analysis, or spectroscopy, can be used to identify the appearance of new forms first identified by observing changes in morphology.

Morphology Prediction and Other Computational Strategies

With the objective of predicting the morphology of crystals, several models have been developed. One of the first models for predicting crystal morphology is based on

the general Law of Bravais (123), which states that crystal faces with the most morphological importance have the greatest interplanar distance, d_{hkl} . The Bravais–Friedel–Donnay–Harker (BFDH) model predicts that the morphological importance of a face is proportional to the interplanar spacing corrected for extinction conditions and translational repetitions of the crystal space group (123–125). Consequently, the growth rate of any given face is inversely proportional to its interplanar spacing:

$$G_{hkl} \propto \frac{1}{d_{hkl}} \quad (16)$$

where G_{hkl} is the growth rate of a face and d_{hkl} is the interplanar spacing. This model has been used to predict the morphology for many small molecules including compounds of pharmaceutical interest. (3, 73, 120, 126, 127). The observed (Fig. 13a) and predicted morphology (Fig. 13b) of carbamazepine dihydrate shows that the BFDH model correctly predicts the axis of elongation as well as the appearance of the {002}, {200}, and {111} faces. This model, however, did not correctly predict the aspect ratio of the crystal because it is based on geometric parameters solely. It considers neither molecular interactions nor the effect of anisotropic forces, such as intermolecular hydrogen bonding or π – π interactions.

Early work by Hartman and Perdok (128) described crystal growth in terms of the formation of strong bonds between neighboring crystallizing units. Uninterrupted straight chains of these bonds were classified as periodic bond chains (PBC). This theory led to the classification of three types of crystal faces: F-faces (flat), S-faces (stepped), and K-faces (kinked), based on the number of PBCs in a slice thickness, d_{hkl} . K-faces, which had no PBCs present in a slice were shown to be the fastest growing, whereas the F-faces, which had two or more PBCs, grew the slowest. Consequently, the F-faces were the most morphologically important faces. The PBC theory ultimately led to the development of the attachment energy (AE) model (122, 129) which states that the growth rate of a face, G_{hkl} , is proportional to its attachment energy, E_{att} :

$$G_{hkl} \propto E_{att} \quad (17)$$

where the attachment energy can be defined as the energy released when one growth layer (d_{hkl}) crystallizes on the surface of a crystal. The attachment energy can be calculated as the difference between the energy of crystallization (or lattice energy) and the energy of a growth slice:

$$E_{att} = E_{crystal} - E_{slice} \quad (18)$$

The values for the energy of crystallization can be calculated by summation of the intermolecular interactions

Fig. 12 Photomicrographs of CBZ(D) crystals grown in aqueous solutions $C/S = 2.5$ at 25°C . (a) In the absence of surfactant. (b) In the presence of 9 mM STC. (From Ref. 53.)

Fig. 13 Dihydrate carbamazepine morphology: (a) Observed morphology when grown from water, (b) Predicted by the BFDH model, (c) Predicted by the AE model. (From Ref. 53.)

from a central reference molecule and all other molecules within the crystal. Similarly, the energy of a growth slice can be calculated for all molecules in that particular slice.

The AE method has been used to successfully predict the morphology for many molecular crystals, especially those that are dominated by strong anisotropic forces (3, 73, 120, 126, 127). In the case of carbamazepine dihydrate, which is dominated by intermolecular hydrogen bonding (especially along the **b**-axis), this model predicts a morphology much closer to the observed morphology (Fig. 13c) (53). Whereas this method can account for anisotropic forces, predictions are very dependent on the force field chosen to calculate the nonbond intermolecular interactions. Much care should be given to the choice of appropriate force fields for the molecules in question. The force field developed by Lifson and coworkers (130),

which is explicitly parameterized for C, H, N, and O atoms, was used in the AE method prediction of carbamazepine dihydrate (53).

Morphology predictions based on the AE method also assume that crystals are grown in vacuo, i.e., in the absence of solvent. Consequently, the solvent effects on morphology are ignored using this method. Roberts et al. have developed a method that calculates a modified attachment energy that can be used to predict the effects of solvents as well as other additives on crystal morphology (131).

With knowledge of the crystal structure, morphology, and intermolecular interactions present, strategies have been developed for the rational choice of additives that will specifically inhibit the growth of the stable polymorph and enhance the growth of a metastable polymorph (29, 64, 65, 74, 84–85, 132–134). These strategies can also be applied to systems for which a change in crystal morphology is desired to aid in product development or delivery (e.g., creating a prismatic habit when a crystal grows preferentially as a needle). The main features of these strategies are:

1. identification of the fastest growing faces of the stable crystalline modification (from experimental data as well as morphology predictions);
2. characterization of intermolecular interactions along the crystallographic direction with fastest growth;
3. selection of additives that can be incorporated into (or adsorbed onto) the crystalline structure along this direction; and
4. development of experimental methods to investigate the effectiveness of the additive to kinetically stabilize the metastable modification.

The selection of additives can be guided by molecular visualizations of the crystal structure based on geometric fits (29, 90) or binding energy calculations (70, 120, 135).

SOLUTION-MEDIATED TRANSFORMATIONS

Knowledge of the propensity of a metastable solid phase to dissolve in a liquid phase from which a stable solid phase nucleates and grows is crucial in many stages of pharmaceutical development. This is because pharmaceutical solids are designed to be dissolved and to come in contact with solvents from the early stages of development (isolated by crystallization from solution) and during processing (wet granulation, spray-drying, freeze-drying, etc.). Given that the sudden disappearance or appearance of a crystalline modification can threaten process development, characterization of the kinetics and mechanisms of

solvent-mediated transformations is of practical importance. It will provide answers to questions such as: What is the relation between processing conditions and the solid-state modification manufactured? Is there a correlation between dissolution conditions, solid phase(s) dissolving, and concentration of drug dissolved?

The importance of phase transition kinetics, molecular interpretations, and process implications are emphasized by several investigators (29–31, 47, 64, 133, 136–138). Cardew and Davey (30) developed a theoretical framework to investigate solvent-mediated transformations in terms of dissolution kinetics of one phase and growth of a second phase. The model represents the time development of the supersaturation with respect to the stable phase, or solute concentration in solution, and to the solid phase composition during the transformation. This experimental approach involves saturating the solution with respect to the metastable phase under consideration and to monitor both solution concentration and solid phase composition in the presence of the metastable phase, under constant external conditions. More useful information is obtained from the concentration or supersaturation profiles than from the solid phase composition profiles with time because the former is related to the driving forces that regulate the transformation rate and can be used to identify the rate-controlling process: dissolution or growth. A calculated supersaturation profile with growth-limited and dissolution-limited regimes is shown in Fig. 14 for the case in which dissolution and growth are linearly dependent on supersaturation (30, 31). Experimental studies of the phase transitions of organic crystals have shown this model to be applicable in explaining the solution-mediated transformation kinetics of polymorphs (30, 31, 138) and solvents (47) and to be applicable to process development (138).

Fig. 14 Simulation of the supersaturation–time profiles as a function of the relative rates of dissolution and crystallization during a solution–mediated transformation. Generated from a kinetic model developed by Cardew and Davey (30), assuming that both dissolution and growth rates are linearly dependent on their respective driving forces. (Adapted from Ref. 136.)

Table 5 Information on crystallization kinetics and mechanisms provided by various experimental techniques

Techniques	Information
Optical microscopy (inverted microscope)	Study crystallization processes in situ Monitor transformations in suspensions Determine transformation times Screen and characterize additive/solvent interactions with specific crystal faces Identify nucleation mechanisms Measure crystal growth rates
Electron microscopy	Characterize additive/solvent interactions with specific crystal faces Identify nucleation and growth mechanisms
Atomic force microscopy	Study crystallization processes in situ
Interferometric microscopy	Examine surface topography Identify nucleation and growth mechanisms Measure crystal growth rates
Raman spectroscopy	Monitor molecular association processes that direct nucleation and crystal growth
Infrared (FT-IR, NIR) spectroscopy, solid-state NMR Spectroscopy	Monitor structure (polymorphs and solvates), conformation, and intermolecular environment of crystals
Spectrophotometry, chromatography	Monitor concentration of solute in solution and supersaturation
Diffraction, Calorimetry, Spectroscopy	Monitor solid phase composition

Some useful experimental techniques for studying small and large scale crystallization and solution-mediated transformations are summarized in Table 5.

SUMMARY

In this chapter, we have discussed the significance of crystallization mechanisms and kinetics in directing crystallization pathways and have presented numerous examples that confirm the importance of controlling the crystallization events (both nucleation and growth) in the pharmaceutical industry. Advances in computational and analytical techniques now provide access to the molecular events that direct nucleation and crystal growth. Consequently, there is no reason for the development of ill-defined crystallization processes even when the desired product is obtained. Understanding the thermodynamic and kinetic behavior of the system is vital for the design of reliable processes; thus, at least a holistic approach that identifies the relevant experimental parameters is essential. Whereas the objectives of formulation or process development may not explicitly include interpretations at the molecular level, the information concealed in the interfaces present during the process, the structure of solutions, and the solids harvested can be significant in the identification of nucleation and growth mechanisms. However, there may be instances, such as the unintentional isolation of a new crystal structure or morphology with

poor formulation characteristics, where knowledge of the molecular level events could prove invaluable in solving formulation or processing problems. Although the significance of crystallization mechanisms and kinetics has been underestimated in the pharmaceutical industry, we hope that the recent developments in computational and analytical techniques will inspire interest in their application to pharmaceutical systems.

DOSAGE FORMS: NON-PARENTERAL

Shailesh K. Singh

Barr Laboratories, Inc., Pomona, New York, U.S.A.

INTRODUCTION

Dosage form is a drug delivery system designed to deliver the active ingredient to the body and, upon administration should deliver the drug at a rate and amount that assures the desired pharmacological effect. Such dosage forms are manufactured under current good manufacturing procedures (cGMP), using equipment and packaging to ensure product stability. The dosage form must produce the same therapeutic response each time it is administered. To maintain this reproducibility between and within batches, manufacturing procedures are validated under a specific quality assurance program. Non-parenteral dosage forms can be categorized based on the route of administration or physical form. Based on physical form they can be classified as solids, liquids (homogenous and heterogeneous systems), semisolids, and aerosols. Dosage forms can also be categorized based on the route of administration. Solid dosage forms include different types of compressed tablets, granules, troches, lozenges, coated dosage forms, and hard and soft gelatin capsules. Liquid dosage forms include solutions, suspensions, emulsions, and buccal and sublingual sprays. Topical dosage forms are applied to the skin and include ointments, pastes, creams, lotions, liniments, and transdermal patches. Some dosage forms are formulated for application to body cavities, viz. rectal and urethral suppositories and vaginal pessaries. Inhalation aerosols, using metered dose inhalers (MDIs), dry powder inhalers (DPIs) and nebulizers, are used to deliver drugs to the respiratory tract. Nasal route uses solution and suspension dosage forms. Occular route is used to administer solutions and suspensions to the eye for local and systemic effects.

SOLID DOSAGE FORMS

Powders and Granules

Powders are intimate mixtures of dry, finely divided drugs and/or chemicals that are intended for oral administration

or external use. Powders may also be formulated as larger particle sized, free-flowing granules to aid in handling and administration. Bulk powders usually are packed into a suitable wide-mouth container and contain relatively nontoxic medicaments in large doses, e.g., compounded magnesium trisilicate oral powder. Insufflations are medicated powders blown into ear, nose, or throat.

Tablets

Flowability and compressibility are two important parameters essential for successful manufacture of tablets. Flowability determines ease of material flow from tablet hopper to the press. Inadequate flow gives rise to arching, bridging, or rat-holing in hoppers. Powder flow can be improved mechanically by use of force feeders. Flowability can also be increased by incorporation of glidants like fumed silica and talc. Another method involves the conversion of powder to spherical particles by spray drying or spheronization. Tablets are manufactured by dry and wet methods. Dry methods consist of direct compression, slugging, and roller compaction of drug-excipient blends. Directly compressible excipients may be disintegrants with poor flow, e.g., microcrystalline cellulose (Avicel PH102); free-flowing materials which do not disintegrate, e.g., dibasic calcium phosphate (DiPac®); or free-flowing powders which disintegrate by dissolution (e.g., spray-dried lactose, anhydrous lactose, dextrose, sucrose, amylose, etc.). The drug is mixed with excipients in a blender and then compressed directly on a tablet press. Dry granulation by compression or slugging is used for moisture or heat sensitive actives. The powder blends are compressed into compacts or slugs. An alternative method is to squeeze the powder blends into solid cake between rollers called roller compacts. These slugs or compacts are milled and screened in order to produce granules with improved flow. Granulation is the process of particle size enlargement of homogeneously mixed powder ingredients and simultaneously increasing bulk density, flowability, and compressibility of the system. Wet granulation process involves the massing of the powder mix, using a binder and

Table 1 List of commonly used tablet diluent/fillers

Diluent	Properties
Dextrose	Hygroscopic and soft granules; available as anhydrous and monohydrate; anhydrous has poor compression
Dicalcium phosphate	Inexpensive, insoluble in water; commercially Ditas [®] is unmilled while Encompress [®] is of specific particle size (better flow)
Alpha lactose monohydrate	Inexpensive, relatively inert; most widely used; often used with Avicel [®] PH MCC to improve disintegration
Mannitol	Freely soluble, used particularly for chewable tablet; powder form has poor flow and compaction; granular form has good flow
Microcrystalline cellulose	Excellent compressibility, some disintegration properties; available in different grades with specific applications
Sodium chloride	Freely soluble, used for solution tablets
Sucrose	Sweet taste but hygroscopic, may be diluted with lactose

solvent. The solvent should be volatile, nontoxic, and removed by drying. This process is not suitable for hydrolysable and thermolabile drugs. The binder is added in the form of a solution, or added dry or its mucilage incorporated with the powder blend. The choice of liquid depends on the properties of the material being granulated. Water is widely used alone or along with a binding agent. Commonly used nonaqueous liquids are isopropanol and ethanol. Massing process is usually performed in a low or high shear granulator where the liquid is poured or sprayed onto a moving powder bed until a moist mass of finely divided material is formed. This is passed through an oscillating granulator with the appropriate screen size to obtain the required granule particle size. Sometimes both intra- and extra-granular portions are divided to prevent incompatibility between excipient material hiding or better distribution, tableting or dissolution. Tablets require different functional excipients for their manufacture. Diluents are inert bulking agents added to actives to make a reasonably sized tablet. Generally, a tablet should weigh about 50–60 mg and therefore very low dose drugs will require these diluents to make at least a 50 mg tablet. Table 1 lists some commonly used excipients. Adsorbents such as fumed silica and kaolin are sometimes used for holding large amounts of fluids in an apparently dry state. Binders are used as adhesives to bind powder in wet granulation and give strength to compacts during compression. Binders may be incorporated into the dry blend or added as a solution to the mixed powder during wet granulation. Table 2 lists some of the binders commonly used in tableting. Disintegrants are usually added to promote rapid breakup of tablets to increase surface area and aid drug dissolution. Disintegrants can act by different mechanisms such as like swelling and capillary action. Table 3 lists some commonly used disintegrants.

Glidants are materials that are added to tablet formulations to improve flow properties of the granulation. They act by reducing inter-particulate friction (e.g., fumed silica). Lubricants are added to prevent the adherence of granules to the punch and die faces of the tablet press. Many lubricants also facilitate flow of granules. Talc and magnesium stearate are more effective as punch lubricants. Stearic acid works better as a die lubricant. Table 4 lists some commonly used lubricants and glidants.

Specific Types of Tablets

Lozenges: These are compressed tablets formulated, without a disintegrant and must be allowed to dissolve in the mouth. They are used for local activity (throat lozenges) or for systemic effect (vitamins).

Effervescent tablets: These tablets undergo quick dissolution of actives in water due to internal liberation of carbon dioxide. By combining alkali metal carbonates or bicarbonates with tartaric or citric acid, carbon dioxide is liberated when placed in water. They are prepared by the heat fusion technique. Usually a water-soluble lubricant is used to prevent scum formation at the water surface. Sweetness is achieved by the addition of saccharin, since sucrose is hygroscopic and increases the bulk of the tablet, e.g., Rochelle Salt[®].

Chewable tablets: These tablets are preferred for pediatric and geriatric patients who have difficulty swallowing whole tablets. Another advantage is that they do not need water for administration. Mannitol is normally used as the base diluent because of its pleasant taste and texture, and because it can effectively mask the taste of objectionable actives. They are usually prepared by wet granulation and are not compressed very hard. High amounts of flavor are added to increase

Table 2 List of commonly used binders in tableting

Binders	Concentration (wt%)	Properties
Natural gums (acacia, tragacanth)	1–5	Form very hard granules; variability in quality
Cellulose derivatives	2–5	HPMC is the most common; used as wet binders
Gelatin (replaced by synthetic polymers)	5–10	Strong adhesive, hence used in lozenges; gels when cold; not very popular in tropical climates
Glucose	Up to 50	Strong adhesive; but hygroscopic
Polyvinyl pyrrolidone (PVP)	2–20	Soluble in water and some organic solvents; (may vary with molecular weight grades)
Starch mucilage	5–10	Commonly used adhesive; insoluble in dry state
Pre-gelatinized starch	10–25	A better alternative to starch paste
Sodium alginate	0.5–3	Forms hard granules; prolongs disintegration time
Sucrose NF	Up to 70	Hygroscopic; tablet hardens on storage

palatability. Antacids are typically formulated as chewable tablets.

Sublingual and buccal tablets: These tablets are placed under the tongue (sublingual) or the cheek (buccal) and can produce immediate systemic effects by enabling the drug to be directly absorbed through the mucosa by preventing the first pass effect (e.g., isoprenaline sulphate and glyceryl trinitrate). Tablets are small, flat, without a disintegrant, and are compressed lightly to produce soft tablets.

Molded tablets: These are prepared from mixtures of medicinal substances and a diluent usually consisting of lactose and powdered sucrose in varying quantities. The powders are dampened with solutions containing high proportions of alcohol depending on the solubility of the active and filler. The dampened powders are pressed under low pressure in die cavities. Solidification depends upon crystal bridging during the subsequent drying process, and not upon the compaction forces.

Multi-layered tablets: A multilayered tablet consists of several different granulations compressed on top of each other to form a single tablet. They may also be bi-layer when incompatible drug substances are used, e.g., phenylephedrine HCl in one layer and ascorbic acid and paracetamol in another.

Modified Release Dosage Forms

Modified release (MR) has been used to describe dosage forms having drug release characteristics based on time, course, and/or location and are designed to accomplish therapeutic or convenience objectives not offered by conventional or immediate release dosage forms. Drugs for chronic conditions with short half-lives, possessing a good therapeutic index and uniform absorption pattern are ideal candidates for such dosage forms. These are either delayed release or extended release (ER) preparations. ER dosage

Table 3 List of commonly used tablet disintegrants

Disintegrants	Concentration (wt%)	Commercial name; property
Alginic acid and alginates	2–10	Created in situ in effervescent tablets
Carbondioxide		Amberlite [®]
Ion exchange resins		Veegum [®] ; often slightly colored
Magnesium aluminium silicate	Up to 10	Avicel; lubricant properties; directly compressible
Microcrystalline cellulose	Up to 20	Starch 1500 [®] (pre-gelatinized starch)
Starch NF	5–20	Primarily a wetting agent but this aids disintegration
Sodium dodecyl sulphate	0.5–5	Nymcel [®]
Sodium carboxymethyl cellulose	1–2	Primojel [®] ; Explotab [®]
Sodium starch glycolate	2–8 (dry)	Corn, potato, maize are most frequently used
Starch	5–10	Ac-Di-Sol [®] ; It may be used both at inter- and intra-granular portions (1–2%)
Croscarmellose sodium	2–4	Polyplasdone XL [®] , Crospovidone NF
Cross linked PVP	2–5	

Table 4 List of commonly used lubricants and glidants in tableting

Excipient	Type	Concentration (wt%)	Property
Calcium and magnesium stearate	Lubricant	0.25–2	Reduces tablet strength, prolongs disintegration, insoluble in water, excellent lubricant
Stearic acid	Lubricant	1–4	More preferred as a die wall lubricant
Polyethylene glycol	Lubricant	2–5	M.W. 4000–6000, soluble in water, moderately effective
Liquid paraffin	Lubricant	Up to 5	Dispersion problems
Sodium lauryl sulphate (SLS)	Lubricant	0.5–5	Moderate lubricant with wetting properties, used with stearates
Sodium stearyl fumarate	Lubricant	0.5–2	Less sensitive to overblending and compressibility
Magnesium lauryl sulphate	Lubricant	1–2	Water soluble
Talc	Lubricant	1–2	Insoluble but not hydrophobic
	Glidant	0.2–0.3	
Colloidal silica (Aerosil [®] , Cabosil [®])	Glidant	0.1–0.2	Excellent glidant
Starch	Glidant	0.2–0.3	Primarily disintegrant
Microcrystalline cellulose	Glidant	0.2–0.5	Primarily used as diluents/filler

forms allow at least a twofold reduction in dosing frequency as compared to the conventional dosage form. Delayed release dosage forms are designed to release all or a portion of drug at times much later than the time of administration. The delay may be time based or environment specific, as in enteric-coated dosage forms. Some other MR dosage forms include repeat action and targeted release dosage forms. Most controlled release products are good examples of ER dosage forms. These dosage forms can be classified by their mechanism of release and/or type of formulation. Coated beads, granules microspheres, and other particulate systems are pellet type controlled release dosage forms, where the drug is usually coated onto nonpareil beads (low dose) or made from granules composed of the drug (high dose). These pellets are further coated with functional coating agents (Eudragits[®], HPMCs, Surelease[®], etc.) to provide various release characteristics. These pellets can be used to fill capsules (e.g., Ornade Spansules[®]) or compressed at low pressure into tablets (e.g., Theo-Dur[®]). In some cases small mini-tablets of about 3–4 mm diameter can be compressed. These tablets function like pellets and can be used to fill capsules. Microencapsulation is a process of encapsulating microscopic drug particles with a thin wall of coating material. Several coating materials have been used including gelatin, ethylcellulose, and polyvinyl alcohol, e.g., Micro-K-Extencaps[®] (Wyeth–Ayerst Research). Matrix systems are dosage forms where drug substance is combined with hydrophilic cellulose polymers (excipient material), which slowly erode in the presence of

body fluids. On hydration, the polymers behave like a gel and prevent the fast disintegration of the tablet. Diffusion from the gel controls the drug release (e.g., Oramorph SR[®] tablets). A multi-layered tablet consists of several different granulations compressed on top of each other to form a single tablet composed of two or more layers. Each layer is fed from a separate feed frame with individual weight control. Precompression tamping helps in good binding of layers. Also, reduced pressures prevent intermixing of granules during compression. They may be bilayer where IR/ER combination are used or mainly when incompatible drug substances is used. Sometimes the release from individual layers is controlled to give a drug delivery system, such as, Geomatrix[®] system (1). In some cases if the bulk density of the tablet is less than one, it floats in the gastric fluids thus extending the residence time in the gastrointestinal tract (GIT). Such dosage forms are called Hydrodynamically Balanced Systems (HBS), an example being Valrelease[®] (Roche). In some cases the drug is embedded inside inert polymeric matrices with materials such as polyethylene, polyvinyl acetate, and polymethacrylates. The granulations are then compressed into tablets. These inert matrices are excreted in the feces unchanged (e.g., Ferro-Gradumet[®] (Abbott)). Some drugs form complexes resulting in slower dissolution and behave as extended release dosage forms, e.g., Rynatan[®] (Carter-Wallace). A slowly eroding tablet may be granulated with hydrophobic excipients (waxy lipophilic material) so that the drug leaches out over an extended period with an outer shell containing the IR dose (buffered aspirin). In some

cases a cationic or anionic drug solution can react with an insoluble resin to form a complex. This complex can be tableted, encapsulated or suspended in a vehicle, e.g., Tussionex Pennkinetic[®] Extended Release Suspension (Medeva). Osmotic pump drug delivery systems consist of a core tablet coated with a semi-permeable membrane with a fine orifice made by laser beams. The core usually forms two layers containing the active and osmotic agents. In the gastric fluids water is imbibed by the osmotic agent (pull) and then exerts pressure on the drug (push) in solution, out through the orifice. Such dosage forms are independent of pH of the gastric fluids and are termed as gastrointestinal therapeutic systems (GITS), e.g., Procardia XL[®] (Pfizer). Repeat action tablets consist of slow release inner core and a immediate release (IR) as in Repetabs[®] (Schering) or as bilayer IR/ER tablets. Delayed release dosage forms are used for drugs that are destroyed in the gastric fluids, or cause gastric irritation, or are absorbed preferentially in the intestine. Such dosage forms are enterically coated using materials such as cellulose acetate phthalate, shellac, and waxes. The coating allows the drug to release at higher pH (pH dependent) or by enzyme catalyzed reactions, e.g., Erythromycin or Aspirin delayed release dosage forms. Several forms of oral controlled release systems are available in the market; however, most of them are dependent on the rate at which the system passes along the gastro-intestinal tract. This can be overcome by regulating the release of the drug by physical chemical means, or by a process related to the environment in which the delivery system is present at the specific time (2).

Capsules

The word “capsule” is derived from the Latin word *capsula* meaning a small box. Gelatin, a substance of natural origin with unique properties, is the major component of capsules. Gelatin is used because it is nontoxic and readily soluble in biological fluids at body temperature. It has good film forming properties and, as a in water and water–glycerol systems, undergoes reversible phase change from a solution to gel at only a few degrees above ambient temperature. There are two forms of gelatin (A and B) based on the method of manufacture from animal bone and skin. The properties important for capsule shell manufacture are viscosity and bloom strength. Hard gelatin capsules are firm and rigid while soft gelatin capsules are soft and flexible. This is because soft capsules contain a larger proportion of plasticizers like glycerol, sorbitol, propylene glycol, acacia, and sucrose. Varying proportions of plasticizers are added depending on the intended use of soft gelatin capsules. The colorants used consist of soluble and insoluble dyes. Titanium

dioxide and iron oxide pigments are common, although recently aluminum lakes are being used. Preservatives are added to capsules to prevent microbial contamination. Moisture levels are also maintained at low levels to prevent bacterial growth on storage.

Hard gelatin capsules (HGCs)

Hard gelatin capsules are available in sizes ranging from size 000, (the largest) to size 5 (the smallest). The fill weight of capsule and tapped bulk density of the powder blend determines the selection of capsule size. Recently, better techniques for capsule sealing, like, self-locking and have made it possible for a range of materials. The filler material should not react with gelatin. Aldehydes lead to gelatin cross-linking affecting the integrity of the shell and water in the formula can act as a plasticizer. On the other hand, hygroscopic agents can make the capsule shell brittle. Powders filled into hard gelatin capsules should have good flow properties to maintain uniform fill weights during filling operations. Granules and pellets of spherical shape making them free-flowing and nonfriable are good candidates for capsule filling using gravitational systems or specialized dosing chambers to maintain uniform fill weight. In some instances, minitabets (filmcoated, nonfriable) can be filled into capsules to produce specialized dosage forms or to separate incompatible ingredients. A recent innovation in hard gelatin capsule filling is a revival of the old practice of filling liquids or semisolids. The main problem encountered is product leakage. This difficulty was overcome by using self-locking capsules and formulation techniques. The use of mixtures of material which are either thermosoftening or thixotropic in nature has become prevalent. These materials are liquefied by heat or shearing force, and revert to solid state within the capsule shell after filling. Filling machines have been developed to handle such formulations with existing powder filling equipment. This system works with solid, liquid, semisolids, and potent drugs. The application of semisolids filling is also getting prevalent. A more recent innovation in HGCs to fill liquid dosage forms with the use of new machines which heat-seal the caps permanently to prevent leakage as observed with liquid filled HGCs in the past. A good example is the introduction of Licaps[®] (Capsugel) for liquid fills. Capsules made of nongelatin ingredients for materials not compatible with gelatin are also available, e.g., cellulose (Vegecaps[®]).

Soft gelatin capsules (SGCs)

SGCs or softgels are continuous gelatin shells surrounding a liquid or semi-solid fill. These capsules are formed, filled, and sealed, all in one operation. These capsules are

available in different shapes and sizes. SGCs are preferred for drugs with poor compressibility, poor powder flow, mixing problem, unstable or poor solubility in gastric pH, and bioavailability problems. Such drugs can be solubilized or dispersed in a liquid, where dosage uniformity is more accurate. Some drugs that are liquid or that melt during compression are good candidates, if other means of tableting are expensive. Gelatin used in SGCs has lower bloom strength than HGCs. The plasticizer type and concentration controls the mechanical strength of the shell. In general, plasticizer amounts are larger, making them more flexible than HGC shells. Preservatives, colorants, and opacifiers are used in the same manner as in HGCs. Sometimes softgel capsules are enteric coated for drugs which are absorbed in the small intestine. Once the capsule shells dissolve *in vivo*, the drug is available in a liquid or semi-solid form that dissolves or disperses into fine particles with enhanced bioavailability. SGCs can be filled with several materials such as aqueous solutions, nonaqueous solutions, suspensions, pastes, oily solutions of drug, self-emulsifying system, and water-miscible liquids. Materials that cause migration of water or plasticizer from the shell cannot be filled. Surfactants and systems with extreme pH should be avoided.

LIQUID DOSAGE FORMS

Solution

A solution is a homogenous single-phase system consisting of two or more components. Solutions are easier to swallow and are acceptable dosage forms for pediatric and geriatric use. The drug in solution is readily available for absorption and therapeutic response is faster. Solutions, however, are bulky and inconvenient to transport. The stability of actives is poorer than in solids and they provide suitable media for microbial growth. Aqueous solutions are preparations made with water as solvent. Purified Water USP is widely used for most preparations. Some drugs are unstable in water or sensitive to the presence of carbon dioxide or oxygen. Not all substances are completely soluble in water and may lead to precipitation. Several other techniques are used to increase solubility of drugs in solution. Cosolvency is a process of increasing solubility of a drug by using a combination of solvents. Some suitable cosolvents are ethanol, isopropyl alcohol, sorbitol, glycerol, and propylene glycol. If a drug is a weak acid or base, then its solubility in water is influenced by pH. The pH for optimum solubility may not give a stable product. Thus, a compromise must be reached to ensure proper formulation and bioavailability. Suitable

buffer systems may be used if necessary. Solubility of insoluble or poorly soluble drugs can also be increased by addition of surface-active agents. Most surfactants are miscible with solvent system and compatible with other ingredients. Hydrophilic surfactants with HLB values >15 are generally preferred. In some cases complexation of a drug with a material may result in formation of soluble molecular complex. However, such complexation needs to be reversible for the active to cross the biological barrier. Chemical modifications of the drug can also result in more water-soluble derivatives. However, these modified drugs are regarded as new chemical entities. Nonaqueous solutions are used when complete solution is not possible in water or if the drug is unstable. Ethyl alcohol is the most widely used water-miscible solvent for external preparations. Ethyl ether is occasionally used as a co-solvent, in combination with alcohol in the preparation of some colloids. Other solvents such as isopropyl myristate and isopropyl palmitate are solvents with low viscosity and are ideally used in cosmetics preparations. Xylene is present in ear drops for human use to dissolve ear wax.

Liquid formulation additives used include buffers, colorants, flavoring agents, and preservatives. Buffers are dissolved in solvents to resist pH changes. The choice of buffers depends on the pH and the buffering capacity. Most pharmaceutically acceptable buffer systems include carbonates, phosphates, citrates, gluconates, and lactates. Colors are added for attractiveness and product identification. Flavors are added to solutions to increase their palatability, particularly for drugs with unpleasant taste. This is especially useful in pediatric formulations. Flavors also help in product identification and are of natural or synthetic sources. Fruit juices, peppermint oil, and menthol are some examples of flavors. Some flavors are preferred for specific products, e.g., mint is associated with antacid formulas. Similarly, flavors are preferred by specific patient groups, e.g., children prefer fruity tastes and smell, while adults prefer flowery and acid flavors. Preservatives help prevent microbial growth. The choice of preservatives should be based on their performance from a microbial challenge test. Care should be taken to ensure there is no adsorption of preservatives onto product containers or packaging material. Antioxidants are added to prevent degradation of the drug in solution; the amount and type can be determined after careful determination of the degradation pathway and stability testing with different agents. Sucrose is widely used as sweetening agent, because it is water soluble, and stable at a wide range of pH. It has a pleasant texture and soothing effect on the throat. There are several other sweeteners that are less widely used. Artificial sweeteners like sugar alcohols and aspartame are used by diabetic patients.

Types of Liquid Preparations

Draught and elixirs: Draught is a mixture by which one or two large doses of about 50 ml are given. Traditionally, elixirs are solutions of potent or nauseating drugs containing alcohol as a cosolvent (60–70%).

Linctuses: A linctus is a viscous preparation usually prescribed for relief of cough. They usually consist of a simple solution of active in a high concentration of sucrose, often with other sweetening agents.

Mouthwashes and gargles: These are aqueous solutions for prevention and treatment of mouth and throat infections. They usually contain antiseptics, analgesics, and/or astringents. These solutions are used directly or diluted with warm water.

Nasal drops: These are small volume aqueous solutions. They are usually buffered to pH of 6.8 and are isotonic solutions. These drops are used locally as antibiotics, anti-inflammators, and decongestants.

Ear drops: These are simple solutions of drugs in water, glycerol, and propylene glycol for local use in the ear and include antibiotics, antiseptics, cleaning solutions, and wax softeners (xylene).

Enemas: These are available as solutions (aqueous or oily) as well as suspensions for rectal administration of drugs for cleaning, diagnostic, or therapeutic effect.

Lotions: These are available as solutions and suspensions to be applied topically without friction. They may either contain humectant, so that moisture is retained on the skin after application, or alcohol, which evaporates quickly imparting a cooling sensation to the skin.

Liniments: These are intended for massaging the skin. They may contain ingredients such as methyl salicylate or camphor as counter-irritants.

Colloidons: These are prepared from volatile solvents that evaporate quickly leaving a tough, flexible film on the skin that seals small cuts and or holds the active in intimate contact with the skin.

Intermediate solutions: Pharmaceutical solutions are used as intermediates for manufacturing other preparations. Aromatic water is used as a flavoring agent and peppermint and anise waters have some carminative properties. These are manufactured as concentrated waters and are diluted before use. Infusions are prepared by extracting the drug using 25% alcohol without heat. Extracts are similar to infusions, but are concentrated by evaporation. Tinctures are alcoholic or hydro-alcoholic solutions prepared from vegetable materials or from chemical substances. They are relatively weak compared to extracts. Spirits are alcoholic or hydro-alcoholic solutions of volatile substances prepared by simple solution or by admixture of ingredients. These are used

as flavoring agents and may have medicinal value. Syrups are concentrated solutions of sucrose or other sugars to which medicaments or flavoring agents are added. These are bacteriostatic by virtue of their osmotic effect, e.g., simple syrup, USP.

Suspensions

These are liquids consisting of insoluble solid particles dispersed throughout a liquid phase. Most suspensions are ready to use while some are prepared as solids to be reconstituted just before use. Ideally, suspension should be homogenous between the time of shaking and dispensing the required dose. The suspended particles should be small, uniformly sized to give a smooth elegant product free from grittiness. Some insoluble solids are not easily wetted by water and thus need wetting agents to be able to disperse readily throughout the medium. Some wetting agents include surfactants, hydrophilic colloids, and solvents. Surface active agents or surfactants possessing HLB value between 7 and 9 are suitable as wetting agents. Most surfactants are used at concentrations of 0.1%. For oral use Tweens and Spans are commonly used, while sodium lauryl sulphate (SLS) is used for external applications. Some wetting agents may cause foaming and formation of deflocculated systems. Hydrophilic colloids like acacia, bentonite, tragacanth, alginates, and cellulose derivatives function as a protective colloid by coating the surface of the particles and thus imparting hydrophilic character to the solid particles. Solvents such as alcohol, glycerol, and glycols are water-miscible and reduce the liquid/air interfacial tension, increasing wetting.

Flocculation and deflocculation

Flocculation comes from the Latin word *flocculate* meaning loose and woolly. Flocculated systems result in rapid rate of settling because each individual unit is composed of many particles and is therefore larger. However, due to the loose packing of flocs they are easily dispersible on shaking. Deflocculated systems on the other hand are made up of smaller particles whose settling rate is slower, but the settled particles tend to form an irreversible compact and are difficult to redisperse. This phenomenon is called *caking*. For coarse suspensions, a deflocculated suspension will have better uniformity of dose but poorer stability due to formation of cake. Thus, a stable suspension is obtained by preparing a partially flocculated suspension with controlled viscosity so that settling is minimal. Controlled flocculation is achieved by a combination of particle size control, electrolytes to control zeta-potential and by the addition of polymers. Inorganic electrolytes, added to an

aqueous suspension alter the zeta-potential of the dispersed particle. Lowering the zeta-potential sufficiently will result in flocculation. Some of the commonly used electrolytes include sodium salts of acetates, phosphates, and citrates. Use of ionic surfactants may also result in flocculation by neutralization of particle charges. Starch, alginates, tragacanth, and cellulose derivatives are sometimes added to control the degree of flocculation so that the suspension is in a flocculated state and the sedimentation volume is large. Suspensions should exhibit high viscosity at low shear rate and vice versa. Also, the viscosity should be low enough to be poured from the container but should spread evenly, if it is intended for external application. Suspensions for injection should be able to pass through hypodermic needles. Acacia gum is used as a thickening agent for extemporaneously prepared suspensions. Tragacanth forms viscous aqueous solutions, and its thixotropic and pseudoplastic properties make it a better thickening agent than acacia. Sodium alginate is used as a suspending agent but is incompatible with cationic materials. Several cellulose derivatives, such as methylcellulose (Celacol[®]), hydroxyethylcellulose (Natrasol[®] 250), sodium carboxymethylcellulose, and microcrystalline cellulose, disperse in water to produce viscous colloidal solutions and are suitable, as suspending agents. Montmorillonite clays or hydrated silicates like bentonite, veegum, and hectorite readily hydrate and absorb up to 12 times their weight of water. The gels formed are thixotropic and therefore have wonderful suspending properties. Carbopols[®] are synthetic polyacrylic acid copolymers that function as thickening agents at higher pH values.

Buffers are included in suspensions to maintain chemical stability and control tonicity. Density modifiers like sucrose and propylene glycol can be added to prevent large differences in densities that could result in sedimentation. Flavors, colors, and perfumes may be added to improve palatability and appearance of the product. Humectants like glycerol and propylene glycol are added in concentrations of 5% for external applications to prevent the product from drying out after application to the skin. Addition of preservatives is important, particularly when using naturally occurring adjuvants. In some situations sweeteners may be added but their effect on final product viscosity and degree of flocculation should be well understood. Suspensions are normally manufactured using colloidal mills with rotor–stator mechanism to ensure free flowing and evenly dispersed particles. Oral suspensions usually have flavoring agents intended for oral administration. Good examples are milk of magnesia, bentonite, magma, and jellies. All these systems swell and form a gel like consistency with non-Newtonian

characteristics. Topical suspensions like Calamine lotion are for external use only.

Emulsions

These are dispersions of one liquid (dispersed phase) in the form of uniformly divided droplets in another liquid (dispersion medium). Depending on which liquid is the dispersed phase oil-in-water (o/w) or water-in-oil (w/o) systems are obtained. To test the identity, emulsion miscibility, staining and conductivity tests are performed. The choice of emulsion depends on the route of administration and the end use. For oral administration, o/w emulsions are used while for external use, both o/w and w/o systems can be employed. Semisolid o/w emulsions are termed as “creams,” and are easily washable after application. Water-in-oil emulsions have an occlusive effect and are therefore preferred as moisturizing lotions and cleansing agents. The choice of oil depends on the application with some oils like castor and cod liver oil having a therapeutic value. Thus, w/o preparations are greasy, with high apparent viscosity while o/w emulsions are less greasy and readily absorbed and washable. Ideally emulsions should exhibit pseudoplasticity and thixotropy, that is, high viscosity at low shear rates and vice versa. They should be dispensable from containers, bottles, and tubes but at the same time should spread on the skin with light pressure. The rheological properties of emulsions are controlled by the concentration, particle size, and viscosity of dispersed phase, concentration of dispersion phase, and the nature and concentration of the emulsifier. The choice of emulsifying system depends on the route of administration, its HLB value and its toxicity. There is no approved list of emulsifiers but pharmaceutical companies employ emulsifiers approved for use in the food industry. Emulsifiers with surface activity reduce the interfacial tension between the phases, thereby decreasing the need for energy to disperse the internal phase. The surfactants used can be anionic like sodium, potassium, and ammonium salts of long chain fatty acids (e.g., sodium stearate), soaps of di- and tri-valent metal ions (e.g., calcium oleate and amine soaps, sulphated and sulphonated compounds (e.g., SLS). Cationic surfactant, amphoteric surfactants like lecithin, and non-ionic surfactants, like glycol and glycerol esters (e.g., glycerol monostearate), sorbitan esters, polysorbates, fatty alcohol polyglycol ethers (e.g., cetyl or cetostearyl alcohol), fatty acid polyglycol esters are also used. Sometimes naturally occurring materials and their derivatives, such as acacia, semi-synthetic polysaccharides (e.g., methylcellulose), sterol containing substances (e.g., beeswax), and wool fat

(anhydrous lanolin), can also be employed as emulsifiers. Other ingredients used in emulsions are finely divided solids, antioxidants, such as butylated hydroxy toluene (BHT) and butylated hydroxyanisole (BHA), humectants and preservatives like benzoic acid, parahydroxybenzoic acid esters, chlorocresol, and phenoxyethanol. Emulsions can be used orally (o/w) with the therapeutic agent included in the internal phase (as for taste masking bad tasting medicaments). Externally, they can be used as lotions either with therapeutic agents or without (as in cosmetics). Emulsions are made using a variety of equipment depending on the stability requirement and the kind of process used. Both batch and continuous processes can be used. Colloid mills have been used traditionally. However, high-pressure homogenizers, microfluidizers, and ultrasonic homogenizers are being used for manufacturing emulsions.

SEMISOLID DOSAGE FORMS

Ointments, creams, and pastes are semisolid dosage forms intended for topical application. They may be applied to the skin, used nasally, rectally, and vaginally. Most of them contain some form of medicament. Medicated ointments are semi-solid preparations intended for application to skin or mucous membranes. Nonmedicated ointments are used as protectants, lubricants, and emollients. Ointment bases used for ointment preparation are of four types, hydrocarbon bases, absorption bases, water-removable bases, and water-soluble bases. Hydrocarbon bases have emollient properties and are effective as occlusive dressings (e.g., Petrolatum, USP). Absorption bases permit the incorporation of aqueous solutions to form w/o emulsions (e.g., hydrophilic petrolatum and lanolin). Water-removable bases are also o/w emulsions and are water washable (e.g., hydrophilic ointment). Water-soluble bases have no oleaginous component and are referred to as *greaseless* water-washable bases (e.g., polyethylene glycol ointment). The potential for absorption depends on the choice of the bases, and intended use of the medicament. Appropriate selection of ointment bases is important for dermal therapy. Ointments for rectal preparation (e.g., Tronolane[®] ointment for hemorrhoidal analgesia) and vaginal preparations (e.g., Mycelex-7[®] ointment as antifungal) are available in the market. Creams are semisolid emulsions with one or more medicinal agents intended for external use. The so called *vanishing creams* are o/w emulsions with stearic acid and cold creams are w/o emulsions with an oily base. Creams spread more easily than ointments and are preferred by

some patients. Gels are semisolid systems with dispersions of small or large molecules in an aqueous vehicle with a gelling agent e.g., high molecular weight Carbopols[®] that are cross-linked polyacrylic acid. Some gels like milk of magnesia or magma has two phases. These behave as thixotropic systems with the viscosity changing due to a *gel-sol* transition on shaking. Pastes are ointments with large amount of powder levigated into the base and are intended for application to the skin. Pastes are more hygroscopic than ointments and are used to absorb serous secretions. (e.g., zinc oxide paste). Plasters are solid or semisolid masses spread on backing paper, plastic, or fabric. Nonmedicated forms are termed as *adhesive plasters* while medicated plasters provide a therapeutic effect at the site of application. Some medicated plasters are termed as *cataplasms*, e.g., ibuprofen (3) and salicylic acid plasters. Transdermal drug delivery systems (TDDS) are used for delivery of actives through the skin into the systemic circulation. Several methods have been used to facilitate the transport of active through the barriers of the skin. Certain absorption enhancers are used to temporarily increase permeability of the skin for increased delivery. More recently, iontophoretic techniques have allowed the delivery of charged chemicals across the skin using an applied electric field (e.g., amino acids and proteins). Sonophoresis or high-frequency ultrasound is also being studied as a means of effectively enhancing transdermal delivery of drugs. Transdermal delivery systems are of two main types the monolithic matrix system that contains the excess drug dispersed in the polymeric matrix and cast into a matrix with a backing layer and frontal membrane, e.g., Estraderm[®] (Novartis). Membrane-controlled transdermal patches contain drug reservoir in the form of a gel or saturated solution of drug with a backing adhesive and a rate controlling membrane e.g., Transderm-Scop[®] (Novartis). Currently, the market is flooded with a variety of transdermal systems for smoke cessation and hormonal delivery patches. More recently efforts are on to develop transmucosal delivery patches.

OTHERS DOSAGE FORMS

Suppositories are solid dosage forms intended for insertion in body cavities like rectum, vagina, and occasionally in the urethra for local or systemic effects. The length, shape, and weight of these depend on the body cavity it is used for. These melt, soften, or dissolve after application depending on the type of suppository base applied. Cocoa butter base suppositories usually melt in contact with the

body temperature. Other bases, such as polyethylene glycol, glycerin, and soap based suppositories solubilize. Cocoa butter suppositories are hydrophobic, and dissolve oil soluble drugs but absorption is poor in the aqueous rectal fluids. Thus, better absorption is obtained with water-soluble bases. Rectal suppositories can be used for local (hemorrhoids) or systemic effects. Systemic bioavailability is poor and the amount of drug required is more than oral administration. Vaginal and urethral suppositories are usually used for their local effects (e.g., anti-infectives). Rectal suppositories weigh about 2 g and have varying shapes like bullets and torpedoes. Urethral suppositories are thin pencil-shaped with tapered ends. Vaginal suppositories are globularized and weigh about 4–5 g. Generally absorption from suppository bases rectally is better when the rectum is empty. Particle size of solids plays an important role in absorption. Most importantly rectal absorption allows to bypass the first pass effect. Most suppositories are manufactured by molding from melts or by compression.

AEROSOL DOSAGE FORMS

Aerosols are pressurized dosage forms containing one or more active drug dissolved, suspended, or emulsified in a propellant or a mixture of solvent and propellant, which is released on actuation of the valve as a fine dispersion of liquid or solid in a gaseous medium. Aerosols are intended for topical administration; for administration into body cavities; for administration orally or nasally as fine solid particles or liquid mists through the pulmonary airways, nasal passages, or oral cavity (buccal or sublingual). Those that provide an airborne mist are called space sprays; those intended for carrying actives to surface are termed as surface sprays and other are termed foam aerosols. Aerosol consists of product concentrate and the liquefied propellant. The pressure depends on the types and amounts of propellants and the nature and amount of active present. Propellant is a liquefied gas or mixture of liquefied gas, which serves as the solvent, or vehicle. In some cases nonliquefied gases like nitrogen, and carbon dioxide are used. Space aerosols (85% propellant) operate at 30–40 psig at 70°F. Surface aerosols (30–70% propellant) operate between 22–55 psig at 70°F. Foam aerosols operate at a slightly higher pressure. Foam aerosols are emulsions of the propellant and product concentrate. Aerosols can be two-phase systems comprising of a solution of drug in liquefied propellant and a vapor phase of propellant/gas. Some of them are present as three-phase systems, comprising of water-immiscible propellant, an aqueous product

concentrate or drug in suspension/emulsion and a vapor phase. Aerosol containers are made from glass (coated and uncoated), tin, aluminum, and stainless steel containers. There are various forms of spray valves and metered valves (for more accurate dosing of potent drug). Oral aerosols are mostly used via the buccal route, e.g., Nitrolingual[®] spray that emits nitroglycerin at a dose of 0.4 mg per metered dose. The respiratory tract offers several advantages for administration of drugs. Inhalation systems should be capable of producing fine particles, usually <10 µm for effective drug delivery. Inhalation drug delivery has been traditionally used to treat respiratory disease, but in recent times the lung has been used as a portal for administering drugs to the systemic circulation. With their large effective surface area, the lungs offer an attractive route for systemic drugs. Three main dosage forms, viz. metered dose inhalers (MDIs), dry powder inhalers (DPIs), and nebulizers have gained prominence (4). Metered dose inhalers are pressurized systems consisting of drug suspension in a propellant and may contain other additives such as surfactants, antioxidants, and solvents, although some solution systems are available. Traditionally MDIs have been formulated using chlorofluorocarbons (CFCs). These propellants are now being phased out under the terms of the “Montreal Protocol” due to their ozone depleting potential (5). This has resulted in an increasing urgency to reformulate existing MDI formulations with alternative hydrofluorocarbon (HFC) propellants such as HFC-143a and HFC-227. Formulations using the new propellants have recently won FDA approval (Airomir[®], 3M Pharmaceuticals). To offer better coordination between actuation and patient inhalation of the emitted dose, several spacer devices are available (Nebuhaler[®], AeroChamber[®], and Breathancer[®]) with marketed MDI formulation. Recent trends in devices include the breath actuated MDI (Autohaler[®], 3M Pharmaceuticals), where the patient inhalation triggers the dose. Due to the phase out of CFCs and extensive difficulties in reformulating using HFCs, dry powder inhalers, and nebulizers are becoming popular. Dry powder inhalers consist of mixtures of micronized drug and a large particle size carrier (usually lactose). These drug-carrier ordered mixtures are packaged in unit doses (capsules or blisters), as in Spinhaler[®] (Fisons Pharmaceuticals) and Rotahaler[®] (GlaxoWellcome Pharmaceuticals) or as pure drug bulk powder, which can be metered into single doses (Turbohaler[®], AstraZeneca Pharmaceuticals). In many instances the patients inhalation maneuver causes the active particles to separate from the carrier in the air stream. More recently, to overcome intra-patient variability in dosing, active DPIs have been designed (Dryhaler[®], Dura Pharmaceuticals). In these devices, the patient’s breath triggers a deaggregation mechanism, which

separates the drug particles from the carrier, which are then inhaled. Newer fine particle generation technologies, such as spray drying and supercritical fluid extraction, are being used to produce fine particles of drug including proteins and peptides for delivery to the deep lung. This can facilitate the use of inhalation delivery systems for systemic drug delivery. Nebulizers generate fine mists from aqueous and nonaqueous drug solutions, using either compressed air or ultra-sonication. Their main disadvantage is that they are bulky and are not portable. Recent developments in this field have focused on the development of battery operated portable devices, which can nebulize aqueous solution containing minimal, or no preservatives.

PEDIATRIC AND GERIATRIC DOSAGE FORMS

Physiology plays an important role in the development and performance of different functions in the body. It is important to determine their consequence on dosage form development. Pediatric dosing is usually determined by weight and age. FDA classifies the pediatric groups into neonates, infant, child, and adolescent. There are several excipients that have been reported to cause adverse reactions, e.g., azo dyes cause bronchoconstriction, lactose may cause prolonged diarrhea and intolerance, and sweeteners such as saccharin are weak carcinogens. Alcohol is a common solvent for most pediatric OTC liquid products. However, limits on the alcohol content of OTC products have been set to minimize toxicity in children. Oral administration is the preferred route for children. However, children younger than 5 years have difficulty swallowing solid tablets. Thus, oral liquid is the most preferred dosage form in pediatric patients. Liquids are often unstable and have short expiration and accurate dosing is difficult. Recently, there has been increased interest in chewable tablets and “sprinkle” powders in capsule formulations as they are well received by children with dentition. Rectal administration is not popular because of wide variability in absorption. Pulmonary administration is emerging to be a popular delivery mode for children, but needs to be studied further for systemic effects. Transdermal route may be another area to explore for children, since the stratum corneum is well developed in children as in adults. This may be beneficial as an alternate route for children. Pediatric drug therapy has very few drug delivery systems. There has been some inroads made with OTC cough and cold products. However, most industries do not have resources to perform separate studies for safety and efficacy in children (smaller consumer than adults) for new chemical entities. Perhaps FDA should take initiatives to provide pharmaceutical

companies with returns like tax break or patent extension and specific market for such developmental work especially for life threatening diseases (6).

Apart from alterations in the pharmacodynamics (PD) and pharmacokinetics (PK), the geriatric population suffers from a number of chronic conditions and physical limitations. Clinical monitoring becomes very important to titer dosing accurately. Most of their PK and PD processes take a down turn. Absorption is slower from the oral cavity. In general, the aged skin is more permeable to water and other chemicals. However, the clearance to the blood stream is lowered thus distribution may not be complete. Physically, impairment or decline in vision may hinder one's ability for self-medication. Also, swallowing and chewing may be a problem in elderly patients. For example, patients suffering from dry mouth may have difficulty swallowing a tablet or capsule. Similarly, elderly patients who are edentulous (i.e., toothless) are incapable of chewing any tablet dosage form. Although sublingual and buccal tablets are used by the elderly population there is very less emphasis on its effect on bioavailability with aging. Patients with dry mouth condition may feel local irritation with such dosage forms. Capsules like tablets may hinder swallowing and are not advisable for elderly patients. Liquids are easier to swallow, but are usually not packaged as unit dosages. Patients with impaired vision and dexterity may not be able to accurately self-administer the required dose. The transdermal route seems to offer better compliance with elderly patients but bioavailability needs to be determined before using this route. Several alternative dosage forms and packaging techniques are emerging to improve compliance of dosage form in elderly patients. Several types of packaging aids like dosett tray, calendar-packs and med packs are used to remind the dosing schedule for elderly patients. Granules of drug may be easy to swallow. They can be mixed with water or food and swallowed easily. Unit dose packs may still be difficult to use for some elderly patients. Effervescent tablets provide an alternative dosage form. These tablets dissolve in water to form a ready-to-use product. The use of an irregular shaped tablet that prevents it from lying flat may be another form that can help patients with impaired dexterity (e.g., Tiltabs®). Similar to granules the drug may also be presented in the form of a small amount of concentrated solution for the entire dose, e.g., 5 ml Rapamune® concentrated oral solution (Wyeth–Ayerst Research). Such products can be mixed with food or drink. This is similar to the use of a dispersible tablet that forms a uniform stable suspension when dispersed in water. Emerging technology has focussed on newer dosage forms like the use of quick or rapid dissolving technology (RDTs), wherein, the dosage form quickly dissolves in the mouth and rapid absorption of

the drug can occur systemically or even from the mouth (7). Furthermore, compliance in elderly patients has also resulted in the availability of sugar and sodium-free products that are beneficial for such age groups.

NEW DRUG-DELIVERY TECHNOLOGIES

Newer technologies are emerging as we move into the new millennium. These technologies promise to have lots of benefits such as simplifying administration regimens, enhancing compliance, improving clinical benefits, and reducing overall healthcare costs. Rapid-dissolving tablets (RDTs) are designed for patients who have difficulty in swallowing standard tablets/capsules, such as pediatric and geriatric patients. These include the lyophilized foam from Zydis[®] (Claritin Reditabs), Flashtab[®] (Prographarm), Orasolv[®] (Cima Labs), Wowtabs[®] (Shaklee), and Flashdose[®] (Fuisz Technology) (8, 9). Hydrogel based technology offered by Professor Neil Graham of British Technology group for development of several systems including morphine suppositories. Nanocrystal[™] technology offered by Elan Corporation where the crystalline drug (<400 nm) is thinly coated with a surface modifier to impart physical stability. Liquitard[®] is a liquid taste masking sustained release granules as a suspension and is offered by Eurand America (10). Inhale Therapeutics offers proprietary technology for pulmonary delivery of proteins and peptides, using innovations in powder processing to develop formulations for deep lung delivery for systemic and local indications (10). Jago Pharma developed the Geomatrix[®] systems which involves the use of multi-layered hydrophilic matrix systems (10). Several newer excipients are now available as matrices for controlled delivery. These include polysaccharides from Galactomannan such as guar gum and locust bean gum (e.g., Timer_x Technology (11). Considerable research efforts have been towards the development of safe and efficient chitosan-based dosage forms (12). The development of solid-lipid nanoparticles (SLN) have made it possible for delivering drugs with less side-effects, better targeting, and protection from enzymes (13). Zambon group in Europe has developed Timeclock[®] technology that involves coating solid drug with hydrophobic surfactant. Chronotropic drug delivery, which targets delivery to a specific absorption window for local as well as systemic effect. Emisphere[®] technology uses a carrier that binds to drug molecules noncovalently to form a complex (14). These complexes easily cross the membranes and then dissociate to release the active. Theratech uses the Theriform[®] microprinting technology to develop oral and implantable dosage form for

making Microdose[®] tablets (15). Delsys Corporation has revolutionized their Accudrop[®] technology of electrostatic deposition of dry powder to any surface with great accuracy (16, 17). Labopharm Inc. has developed Contramid[®] technology obtained by cross-linking of high-amylose starch in three dimensional network which is combined with the active. Once in the stomach, the tablet surface turns into a gel and the active diffuses at an even rate. PORT[™] (Programmable Oral Release Technology) is a technology platform to resolve drugs with biopharmaceutical problems. PORT[™] is a capsule based system with opportunity to provide multiple prolonged release of one or more drugs. This technology is applicable to a wide variety of drug classes and can be used to achieve difficult PK profiles, e.g., zero order with burst system. Quadrant Healthcare has engineered micron-sized particles with enhanced stability and PK profiles (10). Solidose[®] technology is based on chemically modifying oligosaccharides to make them more hydrophobic. In contact with body fluids they undergo phase change and release the drug. Several self-emulsifying and lipid-based systems have been developed that form micro-emulsions of water-insoluble drugs for oral delivery (18). DanBiosystems has developed a proprietary Targit[®] technology, which involves enteric coating with azo polymers, which degrade only at specific sites by bacterial enzymes. Ethypharm is another company involved with coating of nano- and micro-particles, using supercritical fluid (CO₂) technology, suited for fragile water-soluble molecules (peptides and proteins) (10, 19). Protarga[™] is another company which is involved in the development of dosage form by covalently attaching fatty acids (docosahexaenoic acid or DHA) to actives to create new compounds that can be taken up by cells targeted for treatment. A lot of focus has been directed to tissue engineering that is used to design biological substitutes or regenerate natural tissues for defective or lost tissues and organs through the use of cells and their scaffolds (20, 21). Fentanyl Oralet[®] (Abbott labs) is a lollipop that has painkillers used as preoperative sedative. Several forms of intra-vaginal drug delivery systems like Progestasert[®] system (Alza Corp.) and Dinoprostone[®] vaginal insert have been developed. Implants like the levonorgestrel Norplant[®] device (Wyeth–Ayerst Research) that is incorporated as contraceptive on the upper arm. Similarly, Gliadel[®] wafers (Guilford Pharmaceuticals) are implanted in the brain tumor cells.

CONCLUSION

Non-parenteral dosage forms can be administered by different mechanisms. In recent years there has been a

plethora of emerging drug delivery technology companies. Most of these technologies are addressing issues related to unique delivery systems and selectivity of these systems for affected organs or diseases. However, rarely it is recognized that improvements in drug therapy are a consequence of not only the new chemical entity but also the combination of active and the delivery system (dosage form). Currently the trend is to develop a delivery system and then look for suitable drug candidates to apply. This needs to be changed to gain understanding of what unmet medical need is the active aimed for, the rate, time and site for the active to be delivered and then provide a suitable delivery system. More emphasis should be made on the improvement of drug effect profile. Thus, the future of drug delivery will depend on how they can contribute to drug therapy for unmet medical needs (22).

INTRODUCTION

Over the past several years, the fraction of new drug products that are new chemical entities has steadily decreased, reflecting the tremendous cost required to bring new chemical entities to the marketplace. Increased understanding of drug metabolic and toxicologic factors, such as the effect of the patient age on drug distribution, the genetic factors that may result in dramatic intersubject variability in metabolism, short-term versus long-term exposure toxicities, and the potential for teratogenic, mutagenic, and embryotoxic effects, has increased the scrutiny under which governmental agencies view the new chemical entity. This careful inspection is intended to minimize the possibility of toxic reaction(s) and to demonstrate the safety and efficacy of new drug products. The regulatory process has also resulted in significantly more costly and time-consuming testing prior to commercialization.

This increased emphasis on safety has placed an additional burden on those who are involved in the development of new drugs, while increasing financial pressures have led to the need for decreased development time. The investigation of approved drugs has resulted in enhanced patient safety and therapeutic efficacy by directing research efforts toward the more efficacious delivery of known pharmacologically active agents to the appropriate physiologic site. This trend has caused pharmaceutical researchers to seek the most suitable methods to deliver both new and existing compounds in the most pharmacologically appropriate manner. The methods may be designed to optimize bioavailability, minimize toxicity and side effects, and improve stability. The objective of this article is to present approaches that have been employed to improve bioavailability and/or minimize the toxicity and side effects of various drugs.

A rational approach to dosage form design requires a complete understanding of the physicochemical and biopharmaceutical properties of the drug substance.

For example, the successful design of an efficacious oral dosage form requires an understanding of the pathways of physiologic disposition of the drug. Some of the physiologic factors associated with drug disposition are illustrated in Fig. 1 (1). On oral administration of an immediate release dosage form (the most common delivery system), the dosage form must disintegrate, the drug must dissolve in the gastrointestinal (GI) fluids, cross the GI mucosa, enter the mesenteric blood system, and pass through the liver prior to reaching the systemic circulation and the site of action. The drug may be metabolized by GI fluids, by enzymes in the gut wall, or by hepatic metabolism prior to reaching the systemic circulation (Fig. 2) (2). The net result is incomplete bioavailability due to first-pass metabolism (inactivation), and/or metabolic formation of a pharmacologically active species.

The physicochemical and biopharmaceutical properties of the drug can have a tremendous impact on its bioavailability and, hence, on its efficacy and toxicity profile. Thus, understanding these parameters is often tantamount to the selection and development of the optimum dosage form.

These properties of the drug are its:

- pH solubility profile and dissolution rate
- Partition coefficient between lipoidal barriers and aqueous physiologic media
- Stability and/or degradation rate in the physiologic fluids
- Susceptibility to metabolic inactivation
- Mechanism of transport through biologic membranes.

The aqueous solubility of a drug in the 2–8 pH range has a direct influence on its oral and parenteral formulations. A drug with poor solubility (i.e., less than 0.1 mg/ml) in acidic media may show poor and erratic oral bioavailability due to the dependency of absorption processes in GI fluids. Intravenous dosing requires that the drug be administered in a soluble form. The adjustment

Fig. 1 Physiological factors associated with bioavailability. (From Ref. 1.)

Fig. 2 A drug, given as a solid, encounters several barriers and sites of loss in its sequential movement during gastrointestinal absorption. Dissolution, a prerequisite to movement across the gut wall, is the first step. Incomplete dissolution or metabolism in the gut lumen or by enzymes in the gut wall is a cause of poor absorption. Removal of a drug as it passes through the liver further reduces absorption. (From Ref. 2.)

of pH, the addition of a cosolvent or a ligand for complexation, or the formation of an emulsion may permit solubilization, but each of these techniques has limitations. Rapid intravenous administration of a solubilized drug can result in rapid dilution in an environment in which the drug is insoluble, resulting in incomplete availability and a delayed response due to the formation of particulate matter within the vascular system.

Poor aqueous solubility is not always a limitation; in fact, it may be a desirable feature for a sustained effect after oral or parenteral administration. Oral sustained release may be achieved if the drug combines poor aqueous solubility with the ability to be adsorbed throughout the GI tract. Parenteral sustained release can be achieved after intramuscular administration of a suspension of a drug with low solubility under physiologic conditions or from a drug that precipitates from an aqueous vehicle or that forms a reservoir or depot from an oil-containing dosage form.

The lipid-aqueous partition coefficient of a drug molecule affects its absorption by passive diffusion. In general, octanol/pH 7.4 buffer partition coefficients in the 1–2 pH range are sufficient for absorption across lipoidal membranes. However, the absence of a strict relationship between the partition coefficient of a molecule and its ability to be absorbed is due to the complex nature of the absorption process. Absorption across membranes can be affected by several diverse factors that may include the ionic and/or polar characteristics of the drug and/or membrane as well as the site and capacity of carrier-mediated absorption or efflux systems.

Compounds that are intended for oral administration and can undergo rapid degradation at low pH may require protection from the acidic environment of the stomach. Protection can often be afforded by administering the drug in the form of an acid-insoluble chemical species or in a dosage form with an acid-resistant coating. The insoluble chemical species must remain insoluble and unavailable for solution degradation as it passes through the stomach and must dissolve upon reaching the chemically more stable environment of the intestine at a higher pH. To be effective, an acid-resistant coating must remain intact and protect its contents until it reaches the required pH to dissolve the coating and release the contents in the intestine where the drug may be more stable.

Metabolic inactivation of a compound following oral administration can occur in the GI lumen, the GI mucosa, or the liver. The site of metabolism and the susceptibility of the metabolic processes to saturation are factors that may influence oral bioavailability. Occasionally, some of these factors may be altered to

optimize oral bioavailability. For example, segment specific metabolic sites within the GI tract may be avoided through the use of pH-dependent coating materials that rely on the local pH environment of the GI tract to release the drug. Absorption from the lower colon and rectum can reduce exposure to the portal circulation and the first-pass inactivation that can occur in the liver and, thus, provide the opportunity to improve systemic availability following oral administration. Enzyme systems may be saturated by the rapid release of the contents of the dosage form at a local site or by coadministration within the dosage form of a competitive inhibitor.

Once the physicochemical and biopharmaceutical properties of the drug are determined and the desired plasma concentration profile is defined, the pharmaceutical scientist can select and develop an efficacious dosage form by utilizing a formulation approach, a prodrug approach, a device approach, or an alternative administration route approach.

FORMULATION APPROACH

Use of formulation techniques can improve the bioavailability and/or minimize the toxicity and side effects of drugs. Factors to consider include those that impact on solubility and dissolution rates, chemical and enzymatic stability, and absorption capability.

Several parameters, including particle size, crystalline habit, and salt form, can affect the solubility and dissolution rates of the drug. The effect of particle size on the dissolution rate of relatively insoluble compounds becomes significant when the drug is administered as a suspension or solid dosage form and the material is well dispersed within the GI tract. However, caution must be exercised when compressing the material into a final dosage form because excessive force can result in particle agglomeration and an actual increase in the effective particle size.

Polymorphism is the ability of a chemical species to crystallize in more than one distinct crystal habit. The pharmaceutical applications of polymorphism have been reviewed by several authors (3–5). The differences in dissolution rate and solubility that polymorphs can produce may have a dramatic impact on bioavailability when dissolution is the rate-limiting step in the absorption process.

Tawashii (6) investigated the GI absorption of two polymorphs of aspirin, the stable and metastable forms, forms I and II, respectively. He found that the metastable

form produced a 70% higher total serum salicylate levels than the stable form I.

The selection of a salt form directly influences the physicochemical and biopharmaceutical properties of a compound. The impact of salt selection has been reviewed (7–9). Nelson (10) examined the dissolution of theophylline salts and commented on their impact on oral administration. The dissolution rates of the theophylline salts proceeded independently of the pH of the medium but was governed by the diffusion layer pH. The choline and isopropanolamine salts dissolved three to four times faster than the ethylenediamine salt and produced higher and prolonged blood levels.

For highly insoluble amine bases, such as ergotamine and certain antimalarials, the drug may precipitate in the small intestine as soon as the pH rises following stomach emptying. The authors' experience has been that committing the effort and expense required to develop a new, more soluble salt form of this type of drug may be futile, especially if the new salt is only two to three times more soluble than existing salts. Thus, the selection of the most appropriate salt form should be made early in the development process to optimize bioavailability.

The stability of a drug in the gut is influenced by both chemical and enzymatic factors. Protection from chemical degradation may be accomplished via coating techniques, and enzymatic protection may be achieved with enzymatic inhibitors.

An enteric coating protects the drug during transit through the acidic medium of the stomach. Upon entering the higher pH environment of the duodenum, the coating is dissolved, and the drug becomes available for absorption. Such a coating also provides protection for the gut mucosa when the drug is capable of producing GI irritation. This method has been employed for a number of drugs, including potassium chloride, ammonium chloride, aspirin, diethylstilbestrol, erythromycin, and divalproex. Nishimura et al. (11) employed enteric coating of levodopa to improve its bioavailability. Levodopa is absorbed from the upper portion of the small intestine but undergoes rapid degradation in the intestinal mucosa by levodopa decarboxylase. The authors developed an enteric-coated dosage form with an effervescent core. The dosage form remains intact through the stomach, dissolves upon reaching the small intestine, and bursts open due to the effervescence of the incorporated sodium bicarbonate (Fig. 3). The rapid release in the duodenum results in concentrations of levodopa sufficient to saturate the enzyme at the absorption site.

The limitations of enteric-coated dosage forms include the possibility of duodenal irritation from caustic drugs and an increase in intersubject variability due to

Fig. 3 Relationship between the dissolution parameter t_{90-10} of effervescent enteric tablets of levodopa and the amount of sodium bicarbonate formulated in the tablet. The number of strokes was fixed at 5/min and the pH was 7.5. Key: (●) = uncoated tablet; (○) = enteric tablet. (From Ref. 11.)

the presentation to the small intestine of a dosage form that needs to undergo disintegration and dissolution versus a disintegrated and partially dissolved drug substance.

Enzyme inhibitors compete with the active drug for the enzyme and, thereby, reduce the degradation of the drug and deliver it more efficiently to the systemic circulation. An example is the carbidopa–levodopa combination. Carbidopa competes for levodopa decarboxylase, thereby reducing the levodopa degradation and improving the low bioavailability of levodopa.

Alternatively, the enzyme in the gut can be utilized to control the release of the active drug in the gut. For example, sulfasalazine, which is employed in the treatment of ulcerative colitis, is a combination of sulfapyridine and 5-aminosalicylate chemically linked via an azo bond. It remains absorbed and intact throughout the GI tract until it reaches the large intestine, where bacterial azoreductase enzymes degrade the azo bond and release sulfapyridine and 5-aminosalicylate to act locally on the lesions.

Altering the availability for absorption permits tailoring of the concentration-time profile for a drug. In the case of synthetic contraceptive steroids and theophylline dosage

forms, the approach should be to slow the release rate so that undesirable spikes in the plasma levels are minimized. This effect can be accomplished with a sustained-release formulation. In formulating a drug in a sustained-release dosage form, the following must be taken into consideration: the effective drug plasma level, the rate of absorption of the compound, the rate of elimination of the compound, and the site(s) of absorption. Having established these parameters, calculating the required release rate from the dosage form is a relatively simple matter and formulation techniques are readily available to produce the desired release rate. Predicted plasma levels for a steroid drug administered in sustained and conventional dosage forms are shown in Fig. 4.

The mechanism of absorption must always be evaluated when a sustained-release dosage form is considered. A drug that is passively absorbed throughout the GI tracts is an ideal candidate for sustained release. Drugs such as riboflavin, folic acid, aminopenicillins, amino- β -lactams and nucleoside analogs, which have windows of absorption due to site-specific and/or active transport processes, may have incomplete bioavailability when formulated in oral, sustained-release dosage forms.

PRODRUG APPROACH

An alternative to the formulation approach is the prodrug approach. A prodrug is defined as a drug that is prepared by chemically modifying a pharmacologically active species to form a new chemical entity that undergoes

transformation to the active species within the body. The modification alters the physicochemical and biopharmaceutical properties of the drug in some beneficial manner.

The ideal prodrug should have the following characteristics:

- Possess no pharmacologic activity
- Be eliminated more slowly than its rate of cleavage to the parent
- Be nontoxic
- Be inexpensive to prepare.

Prodrugs can be used to increase or decrease the aqueous solubility, mask bitterness, increase lipophilicity, improve absorption, decrease local side effects, and alter membrane permeability of the parent molecule. For example, chloramphenicol has an aqueous solubility of 2.5 mg/ml, but chloramphenicol sodium succinate, a prodrug, has an aqueous solubility of 100 mg/ml. Hydantoins also possess low aqueous solubilities that result in low and variable availability and precipitation following injection. In an effort to increase the aqueous solubility of phenytoin, Stella et al. (12, 13) prepared the ethyl and triethylamine esters of diphenylhydantoic acid. The esters improved aqueous solubility by adding an amine function to the molecule, and under physiologic conditions, the cyclization to phenytoin is irreversible, rapid, and complete.

The perception of taste requires that some minimum aqueous concentration be exceeded so that the taste can be detected (perceived). As a result, bitterness can be masked by reducing solubility. The technique has been applied to

Fig. 4 Computer simulation of a plasma level-time profile of norethindrone from fast-releasing tablet (---) and sustained release tablet (—), from a dose of 0.5 mg/tablet and an elimination half-life of 3 h.

Fig. 5 Plasma acetaminophen concentration following the oral administration of acetaminophen and its ethyl vinyl ether prodrug. Dog 1 received 10 mg/kg doses of acetaminophen (○) and the prodrug (□). Dog 2 received 25 mg/kg doses of acetaminophen (●) and the prodrug (■). The 0.5-h prodrug and 8-h acetaminophen samples for dog 2 could not be obtained. (From Ref. 14.)

acetaminophen by blocking the phenolic substituent with ethyl vinyl ether (14). Chemical hydrolysis to acetaminophen is rapid in the acidic conditions of the stomach. Plasma acetaminophen concentrations in dogs following oral administration of acetaminophen and the prodrug were found to be similar (Fig. 5).

Membrane permeability is governed in part by the lipophilicity of a compound. Highly polar compounds have low lipophilicities and, therefore, low membrane permeability. Epinephrine is a compound of this type. It is very effective in the treatment of glaucoma, but it produces a myriad of side effects. Ocular side effects include hyperemia, mydriasis, corneal edema, and allergic sensitivity. Systemic side effects, such as cardiac arrhythmias, elevated blood pressure, cerebral vascular accidents, dizziness, fear, and restlessness, are observed frequently. In an attempt to enhance the absorption and minimize the side effects of epinephrine, a prodrug, the dipivaloyl ester, was synthesized (15). It was found to be devoid of cardiac symptoms, with no effect on heart rate or blood pressure (Fig. 6) and was effective in lowering intraocular pressure (IOP) (Fig. 7).

On the other hand, highly lipophilic compounds, such as hormones, can be solubilized via the prodrug approach. For example, the rate of transdermal absorption of the highly lipophilic drug, testosterone, was enhanced over

Fig. 6 (A) The effect of intravenous epinephrine (EPI) and its dipivaloyl prodrug (DPE) on blood pressure in dogs. (B) The effect of EPI and its DPE on heart rate in dogs.

50-fold by forming water-soluble, yet lipophilic, prodrug ester (16). The prodrug testosterone-4-dimethylaminobutyrate was found to penetrate human skin tissue, *in vitro*, 54 times faster than testosterone itself (Fig. 8). Furthermore, the prodrug was found to generate testosterone rapidly in biological fluids by enzymatic hydrolysis (Fig. 9).

Oral administration of aspirin can result in gastrointestinal bleeding. The bleeding has been attributed to local irritation due to the acidic nature of the carboxylic acid substituent. In an attempt to reduce the gastric irritation of aspirin, acylal prodrugs were synthesized (17, 18). *In vitro*, the prodrugs generated rapidly aspirin and in a pH-independent fashion. The conversion to aspirin was very sensitive to changes in dielectric constant: decreases caused a corresponding decrease in the reaction rate. This sensitivity is strongly indicative of an S_N1 mechanism. The authors postulated that GI irritation would be reduced due to blockage of both the charge and the acidic nature of the aspirin.

Fig. 7 The mean effect of one drop of 0.025% solution of the DPE of epinephrine on the intraocular pressure of nine glaucomatous individuals.

DEVICE APPROACH

Controlling the release of medication at the site of action is often desirable, especially for compounds that are absorbed rapidly through mucous membranes or are

Fig. 8 Cumulative amounts of TS (□) and TSBH (■) crossing isolated human skin tissue in Franz cells ($n = 6$). TS was applied as a 10% suspension. TSBH was applied as a 10% solution. In each case, the vehicle was pH 7.4 phosphate buffer (0.2 M). (From Ref. 16.)

Fig. 9 Total plasma levels of TS (radioimmunoassay) after topical application of 1.25 μmol of TS (□) or TSBH (■) to the backs of HRS/J hairless mice $n = 6$. (From Ref. 16.)

removed rapidly from the site of action. The approach normally reduces the systemic side effects of the agent. The application of this approach can be illustrated with the Progestasert and Pilocarpine Ocusert dosage forms.

Diffusion-controlled devices may be designed for continuous release and usually use either a matrix or reservoir construction. In matrix systems, the drug is dispersed randomly throughout a polymer, whereas reservoir devices surround the drug with an intact rate-controlling membrane. Regardless of the method of construction, the system must be safe and biocompatible for biological application.

The Progestasert intrauterine device (IUD) is a contraceptive IUD marketed in the United States. It is a white, T-shaped unit constructed of ethylene-vinyl acetate copolymer containing titanium dioxide. It releases progesterone at a rate of 65 $\mu\text{g}/\text{day}$ for 1 year, controlled by an outer coat of ethylene-vinyl acetate copolymer. Zaffaroni pointed out several advantages to the uterine progesterone system (19). It permits target-specific delivery of a fertility-control agent for up to 1 year by utilizing a single natural hormone at the lowest effective level of release of hormonal activity. The 1-year duration gives improved patient compliance while eliminating the pulsing seen with repetitive oral or injectable regimens. The efficacy of the Progestasert was investigated by Aznar and Giner (20). Their results indicated that the systems are highly efficacious in avoiding accidental pregnancy and result in decreased menstrual blood loss.

The Pilocarpine Ocusert is a contact lens-shaped device that is inserted into the lower cul-de-sac of the eye. It provides continuous release of pilocarpine at a rate of 10 or 20 $\mu\text{g/h}$, over a 1-week period, for the treatment of open-angle glaucoma. The system is capable of producing significant lowering of ocular pressure and constriction of the pupillary diameter (21). Its use greatly enhances patient compliance and the convenience of the therapeutic regimen while reducing local and systemic side effects.

Armaly and Rao examined the clinical effects of the Pilocarpine Ocusert systems with different release rates (22). The systems exhibited a dose-response relationship such that increases in the release rate above 50 $\mu\text{g/h}$ resulted in increased ocular hypotensive effects with no appreciable change in ocular pressure. The reduction in pressure observed at the 50 $\mu\text{g/h}$ rate was comparable with the changes seen after the administration of 4–8% of pilocarpine solutions.

ALTERNATIVE ADMINISTRATION ROUTES

The administration of drugs by alternative routes avoids absorption and metabolic barriers that may be present in the GI tract. The routes can also provide systematic availability when oral administration is contraindicated due to a physiologic condition, or the route may provide for a concentration-time profile that approaches intravenous dosing profiles. The ophthalmic, nasal, pulmonary, buccal, transdermal, and rectal routes provide one or more of these advantages.

The ophthalmic route has been used traditionally for topical application for local effects. However, with the increasing number of peptide drugs being developed, the ophthalmic route has been considered for systemic drug delivery (23). After topical administration in the eye, peptides can be absorbed from the mucosa during tear turnover as well as via the blood vessels of the conjunctiva. The route suffers from the hesitancy of practitioners to place a drug into the eye for any reason other than to produce ophthalmic effects. Another drawback is the sensitivity of the eye to irritation by foreign substances.

Nasal administration produces rapid blood levels and rapid responses that approach those obtained from intravenous dosing. In addition, the absorbed drug does not pass through the liver before reaching the systemic circulation, and, thus, first-pass metabolism is avoided. In recent years, the nasal route has received a great deal of attention as a convenient and reliable route for the

systemic administration of drugs, especially those that are ineffective orally and must be given by injection. Recently, butorphanol tartrate was introduced commercially in a nasal spray dosage form (Stadol NS[®]) for the relief of pain, such as migraine headache (24). It would appear that the nasal route could be considered for drugs that meet the following criteria: are ineffective orally; are used chronically; are used in small doses; and are desirable to have rapid entry to the general circulation.

Published work carried out in many laboratories has shown that, with the notable exception of the peptides, drugs with a wide variety of chemical structures are well absorbed through the nasal membranes of animals and man. It is believed by many authors that *in vivo* nasal absorption of compounds with molecular weights less than 300 daltons is not significantly influenced by the physicochemical properties of the drug molecule (25). Factors, such as the size of the molecules and, in the case of peptides, their ability to hydrogen bond with the component(s) of the membrane, are more important than their lipophilicity and their ionization state. For example, the *in vivo* rate of absorption of the very lipophilic drug progesterone is similar to that observed for sodium benzoate, and the *in vivo* rate of absorption of benzoic acid is independent of the pH of the medium (26).

Although many drugs are absorbed rapidly and quantitatively following nasal administration, peptides have generally shown low bioavailabilities. Hussain et al. examined the nasal bioavailability of leucine enkephalin (27). The low bioavailability of this pentapeptide was attributed to hydrolysis in the nasal cavity, with dipeptides causing significant inhibition of the hydrolysis. They concluded that polar compounds, such as peptides, can cross the nasal mucosa, and that administration of low concentrations results in extensive hydrolysis in the nasal mucosa and that hydrolysis of leucine enkephalin can be reduced by concomitant administration of peptidase labile peptides.

If the presence of a pharmacologic activity for a peptide is the only criterion for its use in therapy, then nasal administration may be employed, even though bioavailability is not 100%. However, when bioavailability, as determined by plasma level profiles, is considered, the nasal route for peptide administration is not optimal unless enhancers are employed. Enhancers may cause irritation and reduced membrane integrity. Other drawbacks of nasal delivery include the small volume permitted (i.e., 0.2 ml or less), the need for highly potent drugs with low doses, the potential for irritation, and the unknown consequences of long-term nasal administration of drugs, adjuvants, and other formulation components.

The buccal and sublingual routes of administration permit rapid delivery to the systematic circulation. Absorption from the buccal and sublingual vasculature and lymphatics bypasses hepatic circulation and, thereby, reduces first-pass metabolism. The driving force of absorption is the high thermodynamic activity of the compounds. Organic nitrates and testosterone have been administered by these routes to produce rapid plasma concentrations and to minimize hepatic metabolism.

The sublingual administration of methyltestosterone was examined by Alkalay et al. (28) The sublingual tablet produced a 50% higher relative bioavailability when compared with the oral tablet or oral solution. The increased bioavailability was attributed to the avoidance of first-pass hepatic metabolism due to absorption from the sublingual vasculature and lymphatics.

The limitations of the buccal and sublingual routes include the requirement for successful candidates to possess high thermodynamic activities, the restrictive size of the buccal pouch and sublingual area, and the concern over the palatability and local irritation by the compound.

Transdermal administration can avoid first-pass metabolism as well as provide a large surface area for continuous-controlled administration of drugs with short biological half-lives and narrow therapeutic indices. The route has been used for nitroglycerin ointments, and transdermal therapeutical systems (patches) have been developed for scopolamine, nitroglycerin, clonidine, estradiol, and nicotine.

Scopolamine can cause side effects of dry mouth, drowsiness, tachycardia, central nervous system (CNS) disturbances, and amnesia if plasma concentrations exceed the levels required to alleviate motion sickness (Fig. 10). The application of scopolamine to the posterior auricular areas (the most permeable anatomical site) via a microporous patch permits constant delivery of 0.5 mg over 3 days to prevent motion sickness and avoid side effects.

The transdermal route suffers from the inability of the skin to deliver large doses, the relatively slow plasma increase when compared with other routes, and the potential for irritation. However, several products utilizing this route of administration are currently on the market. Absorption can be enhanced with molecules that maintain an appropriate hydrophilic-lipophilic balance for efficient passage through the barrier of the stratum corneum (16).

Rectal administration of systemic effect has traditionally been limited to clinical situations where oral intake is restricted due to a physiologic condition (e.g., vomiting) or to compounds that are irritating to the gastric mucosa. The

Fig. 10 Relationship between urinary excretion rate of scopolamine and its pharmacological effects; 10% of a parental dose of scopolamine is excreted in the urine unchanged.

route has been utilized for aspirin, acetaminophen, aminophylline, promethazine, perchlorpromazine, chlorpromazine, and indomethacin. The rectal administration of drugs is limited by increased interpatient variability and patient acceptability.

This section has reviewed some of the dosage form design methods available to the pharmaceutical scientist that have been shown to improve the therapeutic efficacy of certain drugs. The key to optimal dosage form design lies in the prerequisite understanding of the physicochemical and biopharmaceutical properties of the drug and the available routes of administration. Once the compound has been characterized and the problem has been defined, the technology is available to optimize bioavailability.

Corrosion of Pharmaceutical Equipment

Paul K. Whitcraft

Rolled Alloys, Temperance, Michigan, U.S.A.

INTRODUCTION

Corrosion, the degradation of a material's properties or mass over time because of environmental effects, is a costly reality that effects every industry. A study issued by the Federal Highway Administration (FHWA) in 2002 conservatively estimates the annual direct cost of corrosion in all U.S. industry sectors at US\$276 billion. Costs associated with corrosion include cathodic/anodic protection; coatings; inhibitors; corrosion-resistant alloys and materials; and maintenance, repair, and depreciation of equipment. Indirect costs, such as lost productivity, environmental or product contamination, planning and design, and lost opportunities, can easily outpace direct costs by factors of two or more.

It is relatively easy to recognize the impact that corrosion has on chemical process industries (CPI). The FHWA indicates that annual direct costs for the refinery, chemical, petrochemical, paper, and food processing industries total US\$13.5 billion. In the chemical and pharmaceutical sector alone, the conservative estimate given is that corrosion costs are roughly 8% of capital expenditures. The US\$1.7 billion figure for this sector is very conservative because it does not include operating and maintenance costs. Corrosion within these industries ranges from mild (exposure of structures to atmospherical conditions) to very severe (strong acids, high temperatures, and halogen environments). Additionally, these industries use large quantities of water for not only chemical process, but for heating and cooling. The properties of water, a very mild corrodent, make it conducive to the electrochemical nature of corrosion processes. Acceptable performance of corrosion-resistant materials or systems can range from tens of years to weeks.

The control of corrosion in pharmaceutical product processes is largely managed through the use of stainless steel. Rust-free surfaces and cleanliness issues to prevent product contamination have been the primary corrosion concerns. Resistance to mildly aggressive cleaning solutions and saline solutions and the potential for under deposit or crevice corrosion present the most severe service conditions. The high standards of cleanliness necessary for pharmaceutical processes favor the mitigation of corrosion.

CORROSION BASICS

The broadest definition of corrosion is the degradation of a material's properties or mass over time because of the effect of the environment. We can think of this in simpler terms by recognizing this process as the tendency for a material to return to its most thermodynamically stable state. For most metallic materials, this means the formation of oxides or sulfides, or other basic metallic compounds generally considered to be ores. For polymeric materials, the end result could be a variety of simple organic compounds. Only in vacuums or under inert atmospheres can corrosion processes be expected to halt entirely. In most cases, these processes are slow enough to afford useful and practical equipment life.

Corrosion is an electrochemical process and corrosion processes follow the basic laws of thermodynamics. Under controlled conditions, corrosion can be measured, repeated, and predicted. However, because corrosion takes place on an atomic level, corrosion can take place in an accelerated localized fashion, appear as uniform visible attack, or result in subsurface microscopical damage. Normal service environments can rapidly complicate these processes and mechanisms with such variables as pH, temperature, stress, surface finish, flow rates, etc. With the wide range of variables that can come into play, it should not be surprising that corrosion appears to be unpredictable at times.

FORMS OF CORROSION

Corrosion of metallic materials can take on many forms. Understanding and recognizing the basic forms of corrosion are necessary for developing a strategy for mitigation. These concepts can also be utilized in assessing nonmetallic materials. Fig. 1 illustrates these basic corrosion mechanisms.

Uniform Corrosion

The simplest form of corrosion is "uniform" or "general" corrosion. This mode of corrosion is characterized by a uniform metal loss over the entire exposed surface. It is the most predictable and measurable form of corrosion.

Fig. 1 Forms of corrosion.

There are many sources of general corrosion data that list actual or typical rates of corrosion for many materials in common environments. Where data are not available, simple laboratory tests can be conducted to simulate process environments.

The most common way to report uniform corrosion is in terms of metal thickness loss per unit of time, such as inches per year or millimeters per year. Because uniform corrosion is predictable, even moderately high corrosion rates can be tolerated provided a suitable monitoring and inspection system is utilized. For most chemical process systems, general corrosion rates of less than 2 mils per year (MPY) are acceptable. Rates between 2 and 20 MPY (1 mil = 0.001 in.) are routinely accepted as useful engineering materials. In severe environments, rates between 20 and 50 MPY may be economically justified. Rates exceeding 50 MPY are generally not acceptable.

For pharmaceutical applications in particular, the rate of corrosion must be considered not only for the effect on equipment, but where the lost metal has gone. Product contamination can be of concern for other products as well, and when this is an issue, the selection of more corrosion-resistant materials is of utmost importance.

Galvanic Corrosion

When two different metallic materials are electrically connected and placed in a conductive solution, an electrical potential will exist. This potential difference will provide a stronger driving force for the dissolution of the less noble (more electrically negative) material. It will also reduce the tendency for the more noble material to dissolve.

Although the relative differences in potential will change from one environment to another, they remain fundamentally the same because the potential is related to the energy required to oxidize them to metal ions in the given environment. The precious metals of gold and platinum are at the high potential (more noble or cathodic) end of the series, whereas zinc and magnesium are at the low potential (less noble or anodic) end. A galvanic series for a variety of metals in seawater is shown in Table 1.

Erosion Corrosion

Erosion corrosion results in an increased rate of corrosion attack attributable to the velocity of a corrodent over the exposed surface. The movement of the corrodent can be

When Active

associated with mechanical wear. The increased corrosion is usually related to the removal or damage of a protective surface film. The mechanism is usually identified by localized corrosion, which exhibits a pattern that follows the flow of the corrodent.

Fretting corrosion is a specialized form of erosion corrosion where two metal surfaces are in contact and experience very slight relative motion that causes damage to one or both surfaces. Again, in the presence of a corrodent, the movement causes mechanical damage of the protective film, leading to localized corrosion.

A second form of erosion corrosion is the case of cavitation. A type of corrosion familiar to pump impellers, this form of attack is caused by the formation and collapse of tiny vapor bubbles near a metallic surface in the presence of a corrodent. The protective surface film is again damaged, in this case by the high pressures caused by the collapse of the bubbles.

Pitting Corrosion

Pitting corrosion is in itself a corrosion mechanism, but is also a form of corrosion often associated with other types of corrosion mechanisms. It is characterized by a highly localized loss of metal. In the extreme case, a pit can appear as deep, tiny hole in an otherwise unaffected surface.

The initiation of a pit is associated with the breakdown of the protective film on the metal surface. In cases where pit depths increase rapidly, the environment is usually such that no repair or repassivation of the protective layer can be accomplished. In situations where many shallow pits form, the environment is usually one where repassivation of the damaged film can be made, but initiation of new sites occurs on a regular basis.

The localized nature of pitting attack can be associated with component geometry, the mechanics of the corrosion process, compositional inhomogeneity, or imperfection within the material itself. The growth of pits, once initiated, is closely related to another corrosion mechanism, crevice corrosion.

Crevice Corrosion

Crevice corrosion occurs in some environments because the nature of the environment within the crevice becomes more aggressive over time. There is little movement of the corrodent within a crevice. Over time, small changes in chemistry because of minor localized corrosion may become magnified because the solution is not being replenished by the bulk solution.

As a result of a slow initial rate of the corrosion, the pH of the crevice environment may become more acidic, or detrimental ion species may concentrate. As a result of

the low-flow condition, the crevice region may become depleted of oxygen, or preclude the replacement of reacted inhibitors.

Selective Leaching

Selective leaching is the process whereby a specific element is removed from an alloy because of an electrochemical interaction with the environment. Dezincification of brass alloys is the most familiar example of this type of corrosion. It occurs most commonly when there is exposure to soft waters and can be accelerated by high carbon dioxide concentrations and the presence of chloride ions.

The result of this corrosion is the formation of a porous and usually brittle shadow of the original component. Other alloy systems are susceptible to this form of corrosion. Examples include the selective loss of aluminum in aluminum–copper alloys, and the loss of iron in cast iron–carbon steels.

Intergranular Corrosion

As the name suggests, this particular corrosion mechanism attacks those sites where individual grains within a metallic material touch each other. These boundaries are natural regions of higher energy because of the greater frequency of dislocations of atoms from the natural order of the material's structure. In addition, these regions also tend to act as sites for the formation of secondary phases, which are essentially small islands within the matrix that have a chemical composition different from the alloy itself.

Depending on the corrodent and the alloy system, corrosion attack may initiate at these locations because of preferential attack of the secondary phase itself, or attack the surrounding matrix, which was locally dealloyed in forming the secondary phase. Either mechanism will result in the metallic surface being etched along the grain boundaries. As the attack progresses, individual grains are separated from the matrix and the surface layer becomes porous. In severe cases, the surface texture becomes grainy or powdery, leading to more rapid metal loss.

Stress Corrosion Cracking

The mechanism of stress corrosion cracking (SCC) is specific to certain alloys (or alloy systems) in specific environments. It is characterized by one or more crack fronts, which have developed as a result of a combination of the particular corrodent and tensile stresses.

Depending on the alloy system and corrodent combination, the cracking can be either intergranular or transgranular. The rate of crack propagation can vary greatly

and is affected by stress levels, temperature, and the concentration of the corrodent. In some severe combinations, such as type 304 stainless steel in a boiling magnesium chloride solution, extensive cracking can be generated in a matter of hours. In most industrial applications, the progress of SCC is, fortunately, at a much slower pace. However, because of the nature of the cracking, it is difficult to detect until extensive corrosion has already developed, which can lead to unexpected catastrophic failure. Alloy system and corrodent combinations that are known to exhibit SCC are fairly well documented and should be considered in initial design stages.

Apart from the SCC mechanism, stress can assist in other corrosion processes. Because this stress-assisted corrosion is related to tensile stresses, it is logical to expect that it will also accelerate the simple mechanical fatigue process. Corrosion fatigue is often difficult to differentiate from simple mechanical fatigue, but is recognized as a factor when the environment has been judged to have accelerated the normal fatigue process. Such systems can also have the effect of lowering the endurance limit such that fatigue will take place at a stress level wherein, without the environmental effect, fatigue failures would not be expected.

CORROSION MONITORING

The most common method of identifying and monitoring corrosion is visual inspection. Evidence of leakage, staining, or a change in surface appearance can be an indication that some type of corrosion is taking place. Experience with certain types of equipment and processes may help dictate inspection intervals and areas on which to focus the inspection. Records of vessel operation, maintenance, and repair can be helpful in establishing a pattern of performance that will improve predictability and minimize down time.

In areas where general corrosion is the expected form, a simple ultrasonic thickness gage can be utilized to determine the extent of corrosion, based on baseline readings made at installation or previous inspections. The entire unit need not be examined. Attention can be focused on those areas most likely to corrode, such as liquid levels, mixing zones, or areas of high turbulence. Corrosion probes, which can be placed in process equipment or pipelines, can monitor corrosion conditions by measuring an actual corrosion current, or other process parameters known to be related to general corrosion rates. These data can be constantly monitored and recorded to predict equipment wear, or as an alert to upset conditions.

For detection of more localized corrosion, such as crevice corrosion or SCC, other ultrasonic inspection

techniques may be useful. Baseline data generated at the time of installation will also be helpful in evaluating results. One benefit derived from this type of inspection technique is that it can often be conducted with little or no interference with production. Periodic planned visual inspection of equipment utilized under conditions likely to cause stress cracking is also an effective technique, especially when combined with nondestructive inspection techniques such as dye penetrant inspection. It may be necessary to remove coatings or insulation from the equipment surface to facilitate inspection.

CORROSION PROCESSES AND MITIGATION

Electrochemical Nature of Corrosion

Corrosion, in its simplest definition, is the process of a material returning to the natural thermodynamic state. For most metallic materials, this means the formation of the oxides or sulfides that existed before being refined into useful engineering materials.

These changes are electrochemical reactions that follow the laws of thermodynamics. This concept aids in understanding why corrosion processes are time-dependent and temperature-dependent, and its application will indicate ways to mitigate corrosion. Corrosion reactions and rates are affected by ion and corrodent concentrations. One of the most basic corrosion reactions involves the oxidation of a pure metal when exposed to a strong acid. A familiar case is that of placing pure iron in hydrochloric acid. The resulting chemical reaction is quite obvious, with the solution beginning to bubble violently. The chemical reaction can be expressed as follows:

The result of this reaction is evidenced by the gradual disappearance of the iron and the hydrogen bubbles rising rapidly to the surface. On an electrochemical level, there is also an exchange of electrons taking place:

The iron has been converted to an iron ion by giving up two electrons (oxidation), which were picked up by the hydrogen ions. By gaining electrons, the hydrogen ion was *reduced* and formed hydrogen gas. Note that the chlorine atom does not enter into the reaction itself. The transfer of electrons takes place on the metal's surface. Those locations where electrons are being given up are identified as "anodes." The sites where electrons are being absorbed are denoted as "cathodes." A difference in electrical potential exists between these two areas and

a complete electrical circuit is developed. Negatively charged electrons flow in the direction of anode to cathode, and positively charged hydrogen ions in the solution move toward the cathode to complete the circuit. The faster the dissolution of the metal (rate of corrosion) is, the higher is the current flow. On a microscopical level, the sites of the anodes and cathodes can change locations on the surface. In fact, this is exactly what happens when general corrosion takes place, with the anodic areas moving uniformly over the metal's surface.

Anodic reactions in metallic corrosion are relatively simple. The reactions are always such that the metal is oxidized to a higher valence state. During general corrosion, this will result in the formation of metallic ions of all the alloying elements. Metals that are capable of exhibiting multiple valence states may go through several stages of oxidation during the corrosion process.

Cathodic reactions are more difficult to predict, but can be categorized into one of five different types of reduction reactions:

Hydrogen evolution

Oxygen reduction in acids

Oxygen reduction–neutral solutions

Metal ion reduction

Metal Deposition

Cell Potentials

Understanding electrochemical behavior and the possible reactions can help in predicting the possibility and extent of corrosion. A reaction will only occur if there is a negative free energy change (ΔG). For electrochemical reactions, the free energy change is calculated from:

$$\Delta G = -nFE$$

where n is the number of electrons, F is Faraday's constant, and E is the cell potential.

Therefore for a given reaction to take place, the cell potential must be positive. The cell potential is taken as the difference between the two half-cell reactions, the

one at the cathode minus the one at the anode. The half-cell potential exists because of the difference in the neutral state compared to the oxidized state, such as Fe/Fe^{2+} ; or, at the cathode, the difference between the neutral state and the reduced state, as in H^+/H_2 . These reduction–oxidation (redox) potentials are measured relative to a standard half-cell potential. The chart shown in Table 2 lists potentials relative to the H^+/H_2 , which is set as zero.

The larger this potential difference is, the greater is the driving force for the reaction. Whether corrosion does occur, and at what rate, is dependent on other factors. For corrosion to occur, there must be a current flow and a completed circuit, which is then governed by Ohm's law: $I = E/R$. The cell potential calculated here represents the peak value for the case of two independent reactions. If the resistance were infinite, the cell potential would remain as calculated but there would be no corrosion at all. The resistance in the circuit is dependent on a number of factors, including the resistivity of the media, surface films, and the metal itself. As current begins to flow, the potentials of both half-cell reactions move slightly toward each other. This change in potential is called polarization.

Once the corrosion current has been determined, the corrosion current density can be calculated by determining the surface area. However, polarization data can be more useful than just estimating corrosion rates. The extent of polarization can help predict the type and the severity of corrosion. As polarization increases, corrosion decreases. Polarization may be preferential to either the cathodic or anodic reactions. Understanding the influence of environmental changes on polarization can offer insights to controlling corrosion. For example, in the iron–hydro-

Table 2 Standard oxidation–reduction potentials

chloric acid example, hydrogen gas formation at the cathode can actually slow the reaction (increased circuit resistance) by blocking the access of hydrogen ions to the cathode site. This results in cathodic polarization and lowers the current flow and corrosion rate. If oxygen is bubbled through the solution, the hydrogen will be removed more rapidly by combining to form water and the corrosion rate increases significantly. Although this is an oversimplified view of the effects of oxygen, it does indicate that the degree of polarization can be affected by changes in the environment, either natural or induced.

Polarization

There are three basic causes of polarization. They are termed activation, concentration, and potential drop. Potential drop is the change in voltage associated with effects of the environment and the circuit between the anode and cathode sites. It includes the effects of the resistivity of the media, surface films, corrosion products, etc.

Activation polarization is because of a rate-controlling step within the corrosion reaction(s) at either the cathode or anode sites. An example of this can be seen with the H^+/H_2 conversion reaction. The first step of this process, $2H^+ + 2e^- \rightarrow 2H$, takes place at a rapid pace. The second part of this reaction, $2H \rightarrow H_2$, occurs more slowly and can become a rate-controlling factor.

Concentration polarization is the effect resulting from the excess of a species, which impedes the corrosion process, or from the depletion of a species critical to the progression of the corrosion process. The earlier case with an excess concentration of hydrogen gas impeding the rate of reaction is an example of concentration polarization. Although, in this case, it occurred at the cathode, it can also develop at the anode.

Measuring Polarization

Although polarization always leads to lower rates of corrosion, identifying the effects of the environment on polarization of the corrosion circuit is useful in predicting corrosion behavior. It is possible to measure the corrosion current while the corrosion potential is varied.

Most often, it is the anodic polarization behavior that is useful in understanding alloy systems in various environments. Anodic polarization tests can be conducted with relatively simple equipment and the scans themselves can be done in a short period of time. They are extremely useful in studying the active-passive behavior that many materials exhibit. As the name suggests, these materials can exhibit both a highly corrosion-resistant behavior or that of a material that corrodes actively, while in the same corrodent. Metals that commonly exhibit this type of

behavior include iron, titanium, aluminum, chromium, and nickel. Alloys of these materials are also subject to this type of behavior.

Active-passive behavior is dependent on the material-corrodent combination and is a function of the anodic or cathodic polarization effects, which occur in that specific combination. In most situations where active-passive behavior occurs, there is a thin layer at the metal surface that is more resistant to the environment than the underlying metal. In stainless steels, this layer is composed of various chromium and/or nickel oxides, which exhibit substantially different electrochemical characteristics than the underlying alloy. If this resistant, or passive, layer is damaged while in an aggressive environment, active corrosion of the freshly exposed surface will occur. The damage to this layer can be either mechanical or electrochemical in nature.

The behavior of iron in nitric acid underscores the importance of recognizing the nature of passivity. Iron is resistant to corrosion in nitric acid at concentrations around 70%. Once passivated under these conditions, it can also exhibit low rates of corrosion as the nitric acid is diluted. However, if this passive film is disturbed, rapid corrosion will begin and repassivation is not possible until the nitric acid concentration is raised to a sufficient level.

Anodic Polarization

Active-passive behavior is schematically represented by the anodic polarization curve shown in Fig. 2. Starting at the base of the plot, the curve starts out with a gradually increasing current as expected. However, at point A, there is a dramatic polarizing effect, which drops the current to a point where corrosion is essentially halted. As the

Fig. 2 Anodic polarization curve for a material exhibiting active-passive behavior.

Fig. 3 Conditions within the corrosive environment can alter the cathodic polarization curve to create fluctuations between passive and active behavior.

potential is increased further, there is little change in current flow until the next critical stage, point B, where a breakdown of the passive film occurs, and the corrosion current again begins to rise.

Even with an established anodic polarization behavior, the performance of a material can vary greatly with relatively minor changes in the corrodent. This is also illustrated in Fig. 3. Frame 1 illustrates the case where the anodic and cathodic polarization curves intersect much as in materials with no active-passive behavior. The anode is actively corroding at a high, but predictable, rate.

Frame 2 represents the condition often found perplexing when using materials that exhibit active-passive behavior. With relatively minor changes within the system, the corrosion current could be very low as when the material is in the passive state, or very high when active corrosion begins.

Frame 3 typifies the condition sought after when using materials in the passive state. In this example, the cathodic polarization curve intersects only in the passive region, resulting in a stable and low corrosion current. This type of system can tolerate moderate upset conditions without the onset of accelerated corrosion.

CORROSION MITIGATION

The basic principles outlined here can be applied to identified corrosion problems and can provide solutions or alternatives. Corrosion control in many forms and approaches is founded on these concepts.

The principle of cathodic or “sacrificial” protection is founded in the natural potential differentials between different metals. Zinc anodes are intentionally placed in electrical contact with steel structures so that, as they corrode, the steel is protected. In other systems, a current may be applied to the structure to be protected so as to cause the current to flow to an artificial anode.

For similar reasons, it is desirable to build process systems out of the same materials. In systems where contact of dissimilar metals cannot be avoided, it is helpful to have the less noble material possess the largest surface area. By doing so, the corrosion current that is generated is distributed over a much greater area and slows the overall rate of penetration. In many such systems, it is also possible to electrically insulate one alloy network from the other.

Anodic protection finds its basis in the understanding of active-passive behavior. By increasing the potential of the component to be protected, it moves from an actively corroding situation to one where passivity can be induced. Such techniques can be quite cost-effective, but must be applied under well-controlled operating conditions because slight overprotection or underprotection can lead to accelerated rates of corrosion.

The types and varieties of inhibition systems are quite diverse, but also derive their fundamental logic from the principles reviewed here. Inhibitors slow corrosion by increasing polarization at either the anodic or cathodic reactions, or by increasing the electrical resistance of the media.

As an alternative to controlling the corrosion processes, the environmental conditions under which the system is operating may lend themselves to control. Temperature can have a significant influence on the corrosion process. This is not surprising because it is an electrochemical reaction and reaction rates do increase with increasing temperature.

If reducing the temperature is not possible, then it may be possible to eliminate one or more corrodents present, which are not critical to the product process. Halogen ions can be particularly aggressive on many materials and are often present only as a contaminant. Careful control of the pH can also be employed in many processes. There are additional environmental influences on corrosion other than the corrodent itself.

The relative velocities between the component and the media can have a direct effect on the corrosion rate. In some instances, increasing the velocity of the corrodent over the surface of the metal will increase the corrosion rate. When concentration polarization occurs, the increased velocity of the media will disperse the concentrating species. However, with passive materials, increasing the velocity can actually result in lower corrosion rates.

The surface finish of the component also has an impact on the mode and severity of the corrosion that can occur. Rough surfaces or tight crevices can facilitate the formation of concentration cells. Surface cleanliness can also be an issue with deposits or films acting as initiation sites. Biological growths can behave as deposits, or can change the underlying surface chemistry to promote corrosion.

One of the most common and cost-effective methods of preventing harmful corrosion is the selection of more

corrosion-resistant materials. In addition to selecting the proper material, fabricating and finishing the equipment can have critical impact on performance. Variations within the metal surface on a microscopical level influence the corrosion process. Microstructural differences such as secondary phases or grain orientation will affect the way corrosion manifests itself. For corrosive environments where grain boundaries are attacked, the grain size of the material plays a significant role in how rapidly the material's properties deteriorate. Chemistry variations in the matrix of weld deposits are also factors that must be considered in some corrosive environments.

The corrosion engineer can play a major role in system design, material selection, process or environmental control, and remediation. The focus of these efforts should not necessarily be the complete elimination or avoidance of corrosion, but rather the selection of the most cost-effective means of corrosion control and abatement.

MATERIAL SELECTION

The range and the availability of various types of engineering materials of construction continue to grow. As these materials improve, the benefits appear not only in terms of equipment reliability, but also processes pushed to more extreme conditions. These materials of construction can be generally classified as ferrous metals, nonferrous metals, plastics, elastomers, and other nonmetallics.

Ferrous Metals

This group of materials encompasses some of the most widely used construction materials as it includes steels and stainless steels. In pharmaceutical process applications, low-alloy steels are typically limited to structural uses and see little contact with product. Mild steels have been utilized successfully in stills, provided the oxygen content is maintained at very low levels. Tool and die steels may be used in areas where the product is dry and no corrosion is anticipated.

Steel and Stainless Steel

In areas where steels are in contact with the product or raw materials, stainless steels are often used as the workhorse. The production of stainless steel began in the early 1900s. The original efforts in this area were presumably based on the observation that chromium-plated steels parts were highly corrosion-resistant. The end result was the introduction of the ferritic *family* of stainless steels. The first documentation of the development of this class of steel began to appear in the 1920s. The first American Society

for Testing and Materials (ASTM) Specifications for stainless steels were published in 1935.

Today, there are seven basic families of stainless steels with compositions that contain 11–33% chromium, 0–38% nickel, and 0–7% molybdenum as the major alloying elements. These families are:

- Ferritic
- Austenitic
- Precipitation Hardenable
- Superferritic
- Martensitic
- Duplex (Ferritic-austenitic)
- Superaustenitic

Chromium is a metal that readily forms an oxide, which is transparent and happens to be extremely resistant to further degradation. As a further benefit to alloying with steel, it is less noble than iron and thus tends to form its oxide first. For exposure to mild, wet environments, the addition of about 11% chromium is sufficient to prevent “rusting” of steel components, hence the term “stainless.”

Ferritic stainless steels are magnetic, have body-centered cubic atomic structures, and possess mechanical properties similar to carbon steel, although less ductile. These materials are historically known as “400” series stainless as they were identified with numbers beginning with 400 when the American Institute for Iron and Steel (AISI) had the authority to designate alloy compositions. Alloy identification is now formally handled by the Unified Numbering System (UNS), where stainless alloy identification numbers generally begin with “S” followed by a five-digit number. Ferritic stainless steels find little application in the pharmaceutical industry owing to their low level of corrosion resistance and strength.

The corrosion resistance of the martensitic steels is again dependent solely on chromium, and because the carbon contents are generally higher than the ferritic alloys, they are less corrosion-resistant. Nevertheless, the combination of useful corrosion resistance in mild environments coupled with high strengths makes the martensitic stainless alloys candidates for cutting tools, molds, gears, shafts, and ball bearings.

Austenitic Stainless Steels

This family of stainless accounts for the widest usage of all the stainless steels. These materials are nonmagnetic, have face-centered cubic structures, and possess mechanical properties similar to the mild steels, but with better formability. The AISI designation system identified the most common of these alloys with numbers beginning with 300 and resulted in the term *300 series* stainless. Table 3 lists the chemical analyses of some standard

Table 3 Typical chemical compositions of some common stainless and nickel alloys

Alloy	Family	C	Cr	Ni	Mo	N	Nb	Other
430	Ferritic	0.07	16.5	—	—	—	—

austenitic stainless steels and compares them to a few materials from other families of materials.

Once the corrosion resistance plateau in ferritic alloys of 18% chromium is reached, the addition of about 8% nickel is required to cause a transition from ferritic to austenitic. The primary benefit of this alloy addition is to achieve the austenitic structure, which, relative to the ferritics, is very tough, formable, and weldable. The added benefit, of course, is the improved corrosion resistance to mild corrodents. This includes adequate resistance to most foods, a wide range of organic chemicals, mild inorganic chemicals, and most natural environmental corrosion.

Nickel is used judiciously as an alloying element because its cost is substantially higher than chromium. However, type 304 is balanced near the austenite–ferrite boundary for another reason. Compositions similar to type 304 that are unable to form ferrite when solidifying after welding are prone to cracking during solidification and are more difficult to hot work. As a result, adding more nickel to the 18–8 composition offers little benefit from a corrosion standpoint and would be detrimental in other regards.

The next major step in alloying additions comes from molybdenum. This element also provides excellent corrosion resistance in oxidizing environments, particularly in aqueous corrosion. It participates in strengthening the passive film, which forms on the stainless steel surface along with chromium and nickel. A significant benefit is realized with the addition of only about 2% molybdenum. Added directly to the 18–8 composition, the alloy would contain too much ferrite so it must be rebalanced. The resulting chemistry is roughly 16% chromium, 10% nickel, and 2% molybdenum, and is recognized as type 316 stainless.

Austenitic alloys also make use of the concept of stabilization. Stainless types 321 and 347 are versions of

type 304 stabilized with titanium and niobium, respectively. These elements will preferentially combine with carbon that comes out of solid solution during weld solidification. Rather than a loss of corrosion resistance associated with formation of harmful chromium carbides, the carbides of titanium and niobium are not detrimental to corrosion resistance. The austenitic family of stainless also prompted another approach to avoiding the effects of chromium carbide precipitation. Because the amount of chromium that precipitated was proportional to the carbon content, lowering the carbon could prevent sensitization. Maintaining the carbon content to below about 0.035% vs. the usual 0.08% maximum will avoid the precipitation of harmful levels of chromium carbide. This discovery, along with improvements in melting technology, resulted in the development of the low-carbon version of many of these alloys. When first introduced, Extra Low Carbon (ELC) grades (i.e., 304 L and 316 L) required premiums on pricing because of higher production costs. This differential has essentially disappeared in the face of modern argon–oxygen decarburization (AOD) furnaces.

Argon–oxygen decarburization furnaces, utilized as a final refining stage in melting, are designed to permit the bubbling of the molten steel with oxygen, which facilitates the removal of carbon and sulfur. During this process, the exposed surface of the melt is protected with an inert argon atmosphere. This arrangement also permits bubbling with nitrogen gas, which will dissolve as atomic nitrogen into the steel. Nitrogen acts in a fashion similar to carbon by pinning slip planes, thus leading to higher-strength materials.

Modern melting technology is also responsible for another trend in stainless metallurgy. At one time, the permissible chemistry ranges for alloying elements needed to be broad to accommodate inhomogeneity in electrical furnace melts, chemical analysis variations, and

Table 4 Typical mechanical properties of some common stainless and nickel alloys

Alloy	Condition	Tensile (KSI)	Yield (KSI)	Elongation (%)	Toughness (ft lb at °F)
430	Annealed	74	45	28	75 at RT
304 L	Annealed	75	28	55	80 at -300°
316 L	Annealed	75	28	55	110 at -300°

C-276	Annealed	110	55	50	240 at -40°
625	Annealed	120	65	50	35 at -320°

raw material quality. For example, the chromium range for type 304 was 8.0–10.0, and still heats were occasionally missed. With current technology, it is possible to maintain $\pm 3\sigma$ limits on chromium to 0.5% or better. The result is that alloys are currently being produced with 0.50–0.75% less of an alloying element than they were just 15 years ago.

Even with alloying additions such as molybdenum to improve localized corrosion resistance to halogens, the workhorse 304 L and 316 L alloys are susceptible to chloride SCC. This cracking mechanism manifests itself as branched, generally transgranular cracks that are so fine as to be virtually undetectable until it has progressed to catastrophic proportions. This mode of failure can occur when the austenitic alloy is under stress in the presence of halogen ions at temperatures above about 120°F. Studies by Copsen underscored the benefit of very low nickel contents, such as the ferritic stainless steels, or nickel levels in excess of about 20%. In fact, the nickel contents in these two alloys are in the range that tends to crack most quickly in chloride-bearing environments.

Duplex Stainless Steels

Stainless alloys that contain roughly equal amounts of austenite and ferrite are termed duplex stainless. This family of alloys grew out of one basic material originally identified as type 329. They are balanced to contain relatively high chromium contents, with only enough nickel and austenitizers to develop about 50% austenite.

These alloys offer several useful advantages. First, their general corrosion resistance is typically slightly above that of 316 L in most media. In addition, because the nickel content is held low, they offer very good resistance to chloride SCC. In combination with good corrosion resistance, duplex stainless alloys offer higher strengths than those typically found with austenitic steels.

Table 4 compares some typical mechanical properties for common stainless and nickel alloys.

Although more formable than the ferritic alloys, they are not as ductile as the austenitic family of alloys. Welding requires more care than with the austenitic alloys because of a greater tendency toward compositional segregation and sensitivity to weld heat input. Improper fabrication techniques can result in equipment that falls short of expectations for corrosion resistance and mechanical properties.

Superaustenitic

During the 1970s and into the 1980s, there was much attention focused on a family of stainless alloys, which came to be identified as superaustenitic. The foundation for the development of this class of materials was in the development of Carpenter no. 20 stainless, introduced in 1951. Consisting of 28% nickel and 19% chromium with additions of molybdenum and copper, this alloy was first produced as a cast material.

20Cb-3 Stainless became popular in the CPI as an intermediate step between type 316 stainless and the more highly alloyed nickel base materials. In particular, it was a cost-effective way to combat chloride SCC. Because of the high nickel content of 20Cb-3 Stainless, it received a nickel base alloy UNS designation as UNS N08020. However, because the major constituent is iron, it is truly a stainless steel. The superaustenitic term is derived from the fact this composition is so far from austenite–ferrite boundary that, unlike the 300 series stainless alloys, there is no chance of developing ferrite in this material.

The main approach to improving the pitting and crevice corrosion resistance of the basic 35% nickel, 19% chromium, and 2% molybdenum alloy was to increase the molybdenum content. Among the first of the newer alloys introduced was 904 L (UNS N08904), which boosted the molybdenum content to 4% and reduced the

nickel content to 25%. The reduction in nickel content was beneficial as a cost-saving factor, with minimal loss of general corrosion resistance and sufficient resistance to chloride SCC.

The next progression was to raise the molybdenum content to a higher level of 6% and to offset the tendency for the formation of sigma phase by the alloying addition of nitrogen. This concept was introduced with two alloys, 254SMO[®] (UNS S31254) and AL-6XN[®] (UNS N08367). The major benefit of the addition of nitrogen was the ability to produce these alloys in heavy product sections such as plate, bar, and forgings. An additional benefit was derived from alloying with nitrogen in terms of increased pitting resistance. A significant amount of work by a large body of researchers has demonstrated a relationship between pitting or crevice corrosion resistance and alloy content, which is approximated by:

$$\text{Cr}\% + 3.3*\text{Mo}\% + 16*\text{N}\%$$

where increasing values indicate increased resistance. A value in excess of approximately 33 is considered necessary for pitting and crevice resistance to ambient seawater.

Other Stainless

The precipitation-hardenable family of stainless alloys utilizes thermal treatment to intentionally precipitate phases, which cause a strengthening of the alloy. The precipitating phase is generated through an alloy addition of one or more of niobium, titanium, copper, molybdenum, or aluminum. The metallurgy is such that the material can be solution-treated (i.e., all alloying elements are in solid solution and the material is in its annealed or softest state). In this condition, the material can be machined, formed, and welded in the desired configuration. After fabrication, the unit is exposed to an elevated temperature cycle (aging), which precipitates the desired phases to cause an increase in mechanical properties.

As a class, these alloys offer high mechanical properties, although not as high as martensitic low-alloy steels, in combination with very useful corrosion resistance. On average, their general corrosion resistance is below that of type 304 stainless. The corrosion resistance of the PH 15-7 Mo and A-286 alloys approaches that of type 316. The martensitic and semiaustenitic pH grades are resistant to chloride cracking. These materials are susceptible to hydrogen embrittlement. In the pharmaceutical industry, these materials might find useful applications in valve components, bolting materials, or wear surfaces.

The ability of the ferritic alloys to resist chloride SCC is one of their most useful features in terms of corrosion resistance. During the 1970s, developmental efforts were directed at producing ferritic materials that could also

exhibit a high level of general and localized pitting resistance as well.

The first commercially significant alloy to meet this expectation was an alloy containing 26% chromium and 1% molybdenum. To obtain the desired corrosion resistance and acceptable fabrication characteristics, the material had to have very low interstitial element contents. To achieve these levels, the material was electron beam-refined under a vacuum, and was introduced as E-BRITE[®] Alloy. Carbon plus nitrogen contents were maintained at levels below 0.020%.

Materials such as SEA-CURE[®] (S43635) and 29-4C[®] Alloy (S44735) represent the most recent developments in superferritic materials. These alloys do exhibit excellent localized corrosion resistance. Although the superferritic materials alloyed with some nickel have improved mechanical toughness and are less sensitive to contamination from interstitial elements, their availability is still limited to heat exchanger tubing with wall thicknesses below about 0.100 in. This is related to the formation of embrittling phase during cooling from annealing temperatures. Section thicknesses over these levels cannot be cooled sufficiently fast to avoid a loss of toughness.

Cast Stainless Steel

The discussion thus far has been devoted to examining the different families of stainless steel metallurgy. The alloys discussed were wrought materials (i.e., materials that are hot-worked following being cast into ingots). The practice of hot working steels improves the uniformity of their chemical, mechanical, and corrosion-resistant properties. These materials are suited for fabrication by bending and welding.

Cast stainless steels can be divided into the same families as the wrought materials, except for the superferritics. Castings offer the particular advantage of being able to obtain complex shapes without extensive fabrication or machining. Cast alloys usually cost less per pound than the wrought counterpart because the hot working operations are avoided. Cast stainless steels can also have chemistry modifications to enhance properties that would otherwise render them unworkable as a wrought product. Heat-resistant cast alloys, such as HK, usually have high carbon and silicon contents, which improve elevated temperature strength considerably, but at the expense of room temperature toughness. The cast structure of such materials is also less resistant to thermal fatigue than the wrought material.

Although the compositions of the basic austenitic cast alloys are very similar to the wrought versions, the cast versions usually contain significant amounts of delta ferrite. As in the solidification of weld metal, ferrite is

beneficial in reducing the tendency for the material to form cracks during solidification. The ferrite content in CF-8M can approach 20% and can readily attract a magnet. Although high ferrite contents are often not of concern, the ferrite can be attacked preferentially in some environments such as urea, nitric acid, and hydrochloric acid.

The existence of significant amounts of ferrite is one form of segregation that can be encountered in cast stainless alloys. Because cooling rates are generally slow for cast components, other secondary phases can form. Chromium carbide precipitation is a particular concern for many of these materials and, under most circumstances, the casting should be solution-annealed prior to being placed in corrosive service.

NONFERROUS METALS

Nickel Alloys

Nickel is very effective in improving the corrosion resistance of stainless steels and is also utilized as the base material for a number of specialty alloys. By definition, nickel alloys contain more nickel than any other constituent. Alloy 625 has been widely used throughout the CPI for its corrosion resistance to strong acids, including hydrochloric acid, and for its resistance to halogen attack. This material also has excellent high-temperature mechanical properties and is used in gas turbine applications. Another nickel base alloy more familiar to the pharmaceutical industry is alloy C-276. This alloy combines the general corrosion resistance advantages of nickel with the benefits of oxidation and localized corrosion resistance derived from chromium and molybdenum.

Nickel alloys are also austenitic, nonmagnetic under all conditions, and possess formability similar to the austenitic stainless steels. The same welding techniques utilized for stainless alloys can be used for joining the nickel alloys.

Recent additions to the wide range of nickel alloys include materials designed to resist even more severe environments, such as hot halogenated acids, which are likely to induce crevice corrosion. Such materials include alloy 686, alloy 59, and alloy C-2000. These materials contain high levels of chromium (over 22%) and molybdenum (over 15%).

Other Nonferrous Materials

Other significant nonferrous materials include copper, aluminum, and titanium, and their alloys. Copper is resistant to most neutral waters, including seawater, and to strong reducing acids. However, it is not resistant to oxidizing acids, amines, metal salts, and sulfur compounds,

and is also sensitive to erosion from high velocities. Aluminum is useful in resisting atmospherical corrosion and neutral waters, but can corrode quickly in acids or bases. As such, copper and aluminum alloys are used sparingly in the CPI.

Titanium offers a much broader range of corrosion resistance and its applications are similar to those of the superaustenitic stainless steels and some nickel alloys. It has good resistance to pitting and crevice corrosion. Titanium alloys offer good general corrosion resistance to a variety of oxidizing and reducing acids. Although titanium alloys can be fabricated by welding, the required procedures are best suited for shops geared for this type of work. Field fabrication and repair are possible, but do require specialized equipment and procedures.

PLASTICS

This is a huge general category of materials, which includes both thermoplastics and thermosetting polymers. Tabular data on the corrosion resistance of these materials in a wide range of environments are available from a variety of sources. Commonly used materials of construction in the CPI include polyvinyl chloride (PVC and CPVC), polyethylene, polypropylene, polystyrene, polycarbonate, polytetrafluoroethylene (PTFE), fiberglass composite materials, and a variety of epoxies used for coatings or adhesives.

This class of materials can be a solution to handling a wide range of very aggressive chemicals, often resulting in a cost savings over more expensive metallic materials. However, some important differences between these materials and metals can limit their application. First, there is a maximum temperature limitation for these materials, which generally ranges from 120°F to 400°F. Many of these materials are limited to useful service temperatures below 200°F. Second, corrosion of these materials rarely occurs by direct material loss through a chemical reaction similar to that of metallic materials. The degradation of properties is usually the result of permeation by, or absorption of, the corrosive media. This attack can result in embrittlement, softening, blistering, crazing, swelling, dissolution, or some other loss of physical properties. Finally, the mechanical strength of this group of materials is generally lower than that of metal alloys. This can usually be accommodated through design, or with suitable exterior support structures.

Within the pharmaceutical industry, these materials are utilized for bulk acid storage at room temperature, storage of dry powders, piping of potable water, sewer lines, and wastewater treatment. The Food and Drug Administration (FDA) recognizes acceptable materials for food contact in the Code of Federal Regulations (CFR) 21 part 177.

ELASTOMERS

Elastomers or rubbers are also available in a wide variety of chemistries starting with natural rubber and including neoprene, urethane, polyester, silicone, and fluoroelastomers. These materials are subject to the same types of degradation as the thermoplastic materials. Temperature limitations are similar, or perhaps slightly lower.

The widest usage of these materials within the chemical process and pharmaceutical industries is for gasket and sealing applications, linings, flexible tubing, electrical insulation, and drive belts.

OTHER NONMETALLICS

Included in this category are materials such as concrete, chemical-resistant grouts, ceramics, and glass. These materials are highly resistant to chemical attack from most media normally encountered in the chemical process and pharmaceutical industries. In general, their usage is restricted as they tend to be brittle, have poor mechanical properties in tension, and are sensitive to thermal shock.

Chemical-resistant grouts and mortars and ceramic tile systems are very effective in providing cleanable surfaces, such as flooring and walls, and for containment. Ceramics are typically silicate-based materials, but there are also types produced from metallic oxides, nitrides, borides, and carbides. Although they generally have good corrosion resistance, they can be attacked by strong, hot alkalis and acidic fluoride media. The chemical-resistant grouts utilize inorganic binders, fillers, and a hardener. The exact formulation utilized must be based on the resistance to the environment to which it will be exposed.

Glassware and glass-lined equipment also offer excellent resistance to corrosion, similar to that of ceramic materials. In addition to the advantages of corrosion resistance, it also affords a very cleanable surface. Glass-lined vessels are used in the pharmaceutical industry for reactors, mixers, storage tanks, transfer piping, and high-purity water systems.

EQUIPMENT AND SERVICE CONSIDERATIONS

Welding

From an engineering standpoint, the ability to weld stainless steels with relative ease is a major advantage to their usefulness. Weld deposits, because they are cast structures, are subject to discussion regarding corrosion resistance similar to the cast materials. The chemistry of a weld deposit is likely to exhibit segregation and, depending on the alloy and the welding technique employed, may

develop deleterious secondary phases in either the weld or heat-affected zone.

Two ways to address this concern have already been discussed. These involve the reduction of carbon content to low levels and the use of stabilizers to prevent chromium depletion. Either of these methods is typically used for components that are assembled in the field, because subjecting the fabricated unit to an annealing treatment is neither practical or desirable in most instances.

In many cases, a small decrease in the corrosion resistance of weldments is tolerable. When the environment is particularly severe for the alloy being used, the weld may be attacked preferentially. This condition can be exaggerated by the area effects of the more noble base metal compared to the small weld zone. An alternate approach for field welding is to select a higher alloy welding consumable so the weld deposit is more noble than the base metal. Preferential attack can also occur in the heat-affected zone of the base metal. This is typical of weldments made in standard type 304 where the carbon content will lead to chromium carbide precipitation. Of course, this condition cannot be avoided by using a different filler metal and the only remedy is a postweld anneal.

Aside from the actual weld deposit chemistry, welding techniques can have an influence on corrosion resistance. First and foremost, the area to be joined should be clean and free of dirt and grease. Carbonaceous materials will contaminate the weld deposit and will deplete chromium from the alloy. For a similar reason, carbon arc gouging or cutting should be avoided. Contamination from other metals should also be avoided. Although free iron will essentially be melted into the weld deposit unnoticed, rust can affect weldability. At best, it can lead to lack of fusion or porosity and, at worst, it may act as a preferential site for the onset of corrosion. Joint preparation should be accomplished using properly sharpened tooling, and wire brushing should be performed using stainless steel brushes.

Low-melting-point metals are of particular concern. Molten copper, zinc, or aluminum will attack the grain boundaries of austenitic alloys preferentially. Copper alloy clamps or fixtures used to hold work, whereas welding has been known to leave smears of metal that have subsequently caused cracking. Zinc from galvanized steel or paint primers has also been known to contaminate weld joints.

Full-penetration weld joints should also be made. This is a good practice from a strength and fatigue resistance standpoint, but is also a factor in avoiding corrosion. Unfused joints are sites likely to trap corrosive products increasing the likelihood that oxygen or metal ion concentration cells are developed. This will generally mean that joints will have to be beveled if the thicknesses to be joined are in excess of 3/16 in. Beveling joints also insures that adequate filler metal will penetrate to the root in those instances where overalloying is desired.

Finally, the surface finish of the weld area should be similar to that of the base metal. Although a slightly higher roughness is usually unavoidable unless welding is followed by grinding to blend in the weld, minimizing roughness in the weld zone can be beneficial. Weld spatter should be removed by grinding. The weld slag from covered electrodes, which prevents oxidation of the metal during solidification, should be completely removed prior to making a second weld pass or placing the weld in service. Slag deposits on the surface will act as crevices in corrosive service. Removal of heat tints on the surface from bare wire or autogenous welding processes is preferred. In severe service, these areas may be attacked preferentially.

Passivation

Stainless steels offer useful resistance because they tend to exhibit passive corrosion behavior as a result of the formation of protective oxide films on the exposed surfaces. Under normal circumstances, stainless steels will readily form this protective layer immediately on exposure to oxygen. When this protective film is violated or fails to form, active corrosion can occur. Some fabrication processes can impede the reformation of this passive layer, and to insure that it is formed, stainless steels are subjected to "passivation" treatments.

The most common passivation treatments involve exposing the metal to an oxidizing acid. Nitric and nitric-hydrofluoric acid mixtures comprise the predominant usage in stainless steel production. The nitric-hydrofluoric acid mixtures are more aggressive and are typically used to remove the oxide scales formed during thermal treatment. This "pickling" process provides two benefits. First, it removes the oxide scale and passivates the underlying metal surface. Second, because of its aggressive nature, the process will remove any chromium-depleted layer that may have formed as a result of the scale formation.

For passivation treatments other than scale removal following thermal treatment, less aggressive acid solutions are usually employed. The primary purpose of these treatments is to remove contaminants that may be on the component's surface and could prevent the formation of the oxide layer locally. The most common contaminant is imbedded or free iron particle from forming or machining tools. Mechanical polishing can be employed to provide a uniform surface finish and to remove these contaminants. The polishing materials should be used for stainless only as they can carry over small particulates from one part to the next. In addition, the work-hardened state of this fine particulate, even from a stainless vessel, can have a lower threshold for corrosion and act as an initiation site if not removed. A dilute (10%) solution of nitric acid is effective at removing free iron, or similar contaminants. For ferritic, martensitic, or precipitation-hardening grades, a nit-

ric acid solution inhibited with sodium dichromate is used so as not to attack the stainless too aggressively. For the more resistant stainless alloys, phosphoric acid at 1% concentration and citric acid at 20% concentrations are also effective. Other commercially available chelating agents can be employed.

Electropolishing

Electropolishing is actually controlled corrosion, resulting in the uniform removal of the surface layer of metal. Electropolishing is not a passivation treatment, although the process does result in a passive surface. Proper electropolishing technique maintains the part in the electrochemically passive range whereas the passivated layer is only allowed to grow several atoms thick, at most. The electrolyte simultaneously promotes dissolution of this layer. The electropolishing process does remove surface impurities as is accomplished with passivation. During the cleaning and rinsing process following electropolishing, the material does passivate naturally on exposure to oxygen containing rinse water or air. No additional passivation procedure is required.

Electrolytes used for electropolishing are usually proprietary mixtures with contents that are not quantitatively revealed. Any electrolyte will typically have the ingredients to facilitate three different actions of the polishing process. These are: 1) a contaminant, which facilitates the breakdown of a passive film; 2) an oxidizer, which helps form a passivating film; and 3) a highly viscous constituent, which promotes the formation of a diffusion layer. The oxidizer and the contaminant assist in maintaining the part in a pseudo-passive state whereas the diffusion layer control is necessary to promote uniform metal loss. This is illustrated in the potentiodynamic graph shown in Fig. 4. For electropolishing 316 L stainless, the electrolyte will often contain perchloric acid, which can provide both oxidizing power and a halide contaminant. Acetic anhydride may be used to control the

Fig. 4 Anodic polarization curve illustrating the unstable state created and maintained during electropolishing.

Fig. 5 Schematic diagram illustrating how, as electropolishing potential is increased, conditions may change from etching to polishing and, finally, to pitting.

diffusion layer. Stainless and higher nickel alloys might also use nitric acid, sulfuric acid, phosphoric acid, hydrogen peroxide, and methyl alcohol.

Determining the ideal electrolyte ingredients is an important part of the process. Because this is an electrochemical process, other variables to be controlled include the voltage, current density, and solution temperature. As illustrated in Fig. 5, voltages that are too low can cause etching of the surface because of more rapid general corrosion; too high a voltage will result in pitting. Cathode design is important because it is imperative to distribute the current as uniformly as possible over the part's surface.

Rouging

Rouging is a phenomenon of particular interest to the pharmaceutical industry. It is the presence of a surface layer of oxide found on stainless equipment or piping, typically handling high-purity water at temperatures above ambient. This includes stills, steam systems, purified water, and water for injection (WFI). The oxides can range in composition, degree of oxidation, color, texture, and adherence. Although generally shown to be innocuous, the mere presence of these deposits can raise concern.

The rouge itself is typically composed primarily of iron oxides or iron hydroxides, but because these are developing on stainless surfaces, they also contain oxides of chromium, nickel, and molybdenum as well. There are empirical data indicating that resistance to rouging increases with increasing Cr/Fe ratios in the passive layer, and/or the depth of the passive layer itself. Because electropolishing and passivation both increase the Cr/Fe ratio, application of these processes can increase resistance to rouging. Even with such treatments, the passive layer can break down because of the ionizing effect of high-purity water. The low oxygen content of these waters also slows the rate of repassivation and may cause the layer to linger in intermediate states of oxidation.

Repeated cycles of this process result in the entrapment of various oxides in the passive layer, hence the wide variation in colors.

Removal of rouging can be accomplished mechanically, but is usually addressed by chemical cleaning. Repassivation treatments with nitric, phosphoric, citric, or other oxidizing acid solutions have been effective in removing or fully reoxidizing this layer. As with any chemical reaction, the process is time-dependent and can be influenced by temperature. For more resistant rouge patterns, reducing acids such as hydrofluoric or hydrochloric may be used in combination with a passivation treatment. The use of these acids in strong concentrations may etch the surface.

Potentiodynamic polarization studies have been conducted to measure the efficacy of passivation treatments. It has been shown that the breakdown (pitting) potential is raised by passivation or electropolishing techniques, which result in higher Cr/Fe ratios and increased depth of the passive layer. These potentials can be increased by as much as 50–100 mV over mechanically polished or pickled surfaces, and have been equated to increased resistance to rouging. Additionally, breakdown potentials of the 6% molybdenum alloy N08367 were shown to be 400 mV higher prior to enhancing passivation treatments, and another 50 mV higher following such treatments. Such studies would suggest that higher alloys such as N08367 or the C-276 type alloy are highly resistant to rouging.

SUMMARY

This discussion provides for a fundamental understanding of corrosion and corrosion processes. It also offers an overview of both metallic and nonmetallic materials utilized in the construction of pharmaceutical equipment and some of the special considerations in their application. Suppliers of materials and fabrication services are valuable resources of information and should be included in the design process. Because corrosion processes are often complex, the services of corrosion engineering professionals should be considered in the original design or performance analysis activities as part of an in-house team, or on a consulting basis.

Crystal Habit Changes and Dosage Form Performance

A. K. Tiwary

Punjabi University, Patiala, India

INTRODUCTION

A crystalline particle is characterized by definite external and internal structures. Habit describes the external shape of a crystal, whereas polymorphic state refers to the definite arrangement of molecules inside the crystal lattice. Crystallization is invariably employed as the final step for purification of a solid. Use of different solvents and processing conditions may alter the habit of recrystallized particles, besides modifying the polymorphic state of the solid. Subtle changes in crystal habit at this stage can lead to significant variation in raw material characteristics. Furthermore, various indices of dosage form performance such as particle orientation, flowability, packing, compaction, suspension stability, and dissolution can be altered even in the absence of significantly altered polymorphic state. These effects are a result of the physical effect of different crystal habits. In addition, changes in crystal habit accompanied with or without polymorphic transformation during processing or storage can lead to serious implications of physical stability in dosage forms. Therefore to minimize variations in raw material characteristics, to ensure reproducibility of results during preformulation, and to correctly judge the cause of instability and poor performance of a dosage form, it is essential to recognize the importance of changes in crystal surface appearance and habit of pharmaceutical powders. Fig. 1 depicts an overview of the critical stages where changes in crystal habit are likely to appear during pharmaceutical processing.

CRYSTAL HABIT CHANGES

The internal structure or polymorphic state represents the molecular arrangement within a crystal and is manifested in the form of a definite heat of fusion (ΔH_f) value. External structure or crystal habit is the outer description of a crystal and is described by its length, width, thickness, and surface appearance (roughness, smoothness, and porosity). Crystal growth may be impeded by adjacent crystals growing simultaneously or contacting container walls. As a result, the development of plane faces may be inhibited, leading to the formation of a tabular (moderate

development of parallel faces), platy (excessive development of parallel faces), prismatic, acicular (inhibited width), or bladed (flattened acicular) crystal habit.^[1,2]

Thus a single internal structure of a compound can have several different habits. In the case of delayed crystallization, an irregularly shaped crystal may be produced because it is constrained to occupy only the spaces left between already crystallized particles. Such irregularly shaped crystals are described as anhedral or allotriomorphic, and those bound by plane faces are known as euhedral or idiomorphic. However, anhedral crystals do have a regular arrangement of building blocks in the crystal lattice.

Crystallization of a solid may be influenced by formulation and process variables of the crystallization process. However, it is difficult to delineate the role of a process variable on crystal habit because an alteration of the variable often leads to change in both deposition and dissolution rate of the material during the crystal growth phase. In addition, the processes are interactive and not independent of each other. For example, a change in temperature simultaneously alters the viscosity of crystallization solvent as well as saturation level of the solute. Hence an increase in temperature affects both deposition and dissolution rate of the solute on crystal nuclei. Similarly, rate of stirring influences the onset of nuclei formation because of its effect on the temperature of the solution. It also influences the growth of crystals because of the uniform distribution of solute throughout the solution. The net result of an altered variable is usually dependent on more dominant factors such as initial supersaturation level, nature of the co-solvent, crystallizing solvent, cooling rate, etc. Few important factors that alter crystal habit and the anticipated influence of altered habit on dosage form performance are summarized in Table 1.

Changes in polymorphic state as a result of the employment of different crystallization conditions and the influence of these polymorphic states on stability and biological attributes of dosage forms have been receiving focused attention of many researchers. However, not much importance seems to have been given toward crystal habit perhaps because of the complexity of the crystallization process and its ability to simultaneously modify

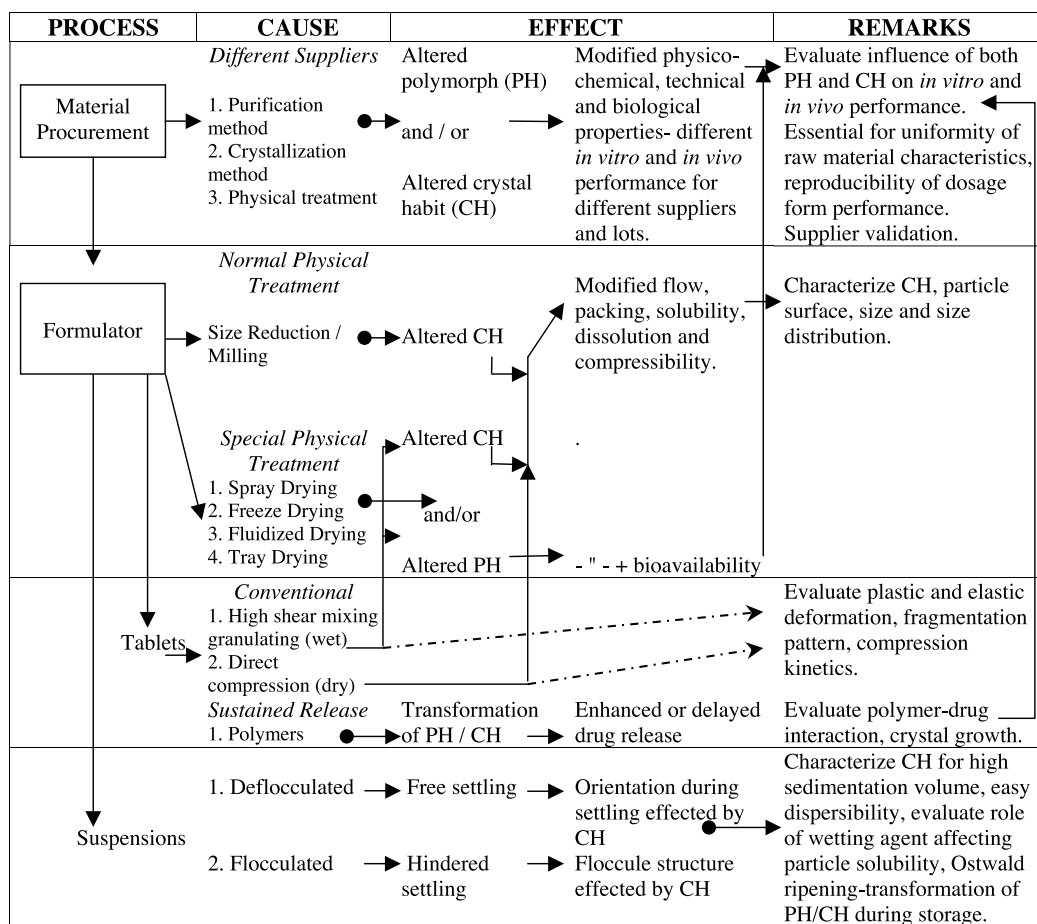

Fig. 1 Flow chart of the cause and effect relationship outlining the importance of crystal habit in dosage form design and performance.

both habit and polymorphic state of compounds. Nevertheless, because of the great impact of this seemingly trivial crystal property on dosage form performance, there is a need to study the important factors that influence crystal habit.

FACTORS INFLUENCING CRYSTAL HABIT

Degree of Supersaturation

The degree of supersaturation of the mother liquor or difference in concentration of solute on opposite sides of a growing crystal influences crystal habit. The effect of supersaturation on the change in habit was described by an equation, $y/x = k\Delta G^n$, where y/x is the ratio of crystal length to breadth, k is a coefficient of proportionality depending on diffusion, ΔG is the degree of supersaturation (moles/1000 mol of solvent at the moment of nuclei for-

mation), and n is a number that depends on the crystallographic classification and the chemical composition of the substance.^[3]

Barium sulfate precipitation has been reported to be controlled initially by nucleation reaction and, finally, by growth reaction. The growth kinetics was represented by the equation:

$$\frac{da}{dt} = -k(C_0 - C)^{2/3}a^q$$

where a is the mean ionic activity of Ba^{2+} and SO_4^{2-} , t is the time, C_0 and C are the molar concentrations of barium sulfate available at t_0 and t , respectively, k incorporates the kinetic constant and the shape factor, and q is proportional to the rate of change of the mean ionic activity and surface of the particle.^[4]

However, Nielsen^[5-7] reported the growth of barium sulfate to be controlled by a chemical reaction in which

Table 1 Influence of process variables of crystallization on crystal habit and dosage form performance

Process variable of crystallization	Possible influence on crystal habit	Possible influence on crystal/dosage form performance ^a
<i>Supersaturation</i>		
1. More saturation or significant solute–solvent interaction	Rate of nuclei formation is greater than crystal growth More growth in one direction producing needle-shaped crystals	Fine particles are produced Needle-shaped crystals exhibit poor flowability and cause bridging in hopper
2. Less saturation or insignificant solute–solvent interaction	Platy crystals are produced	Platy crystals exhibit greater dissolution, but are not preferred for tablet dosage form
<i>Rate of cooling and degree of solution agitation</i>		
1. Rapid cooling	Rapid crystal growth occurs and asymmetric (thin platy crystals) are produced	Platy crystals are not preferred for tablet dosage forms
2. Slow cooling	Rate of crystal growth decreases, and symmetric crystals are produced	Using symmetric, compact crystals gives more predictable and consistent performance
3. High speed of agitation	Even distribution of crystallizing solute on the nuclei produces elongated crystals with small particle size distribution	Desirable particle size range can be obtained; such crystals exhibit good flowability and less sedimentation in suspensions
4. Low speed of agitation or unstirred solutions	Crystallizing molecules deposit on selected crystal face, producing large platy crystals	Crystals with large particle size are unsuitable for formulations
<i>Nature of crystallizing solvent</i>		
1. More affinity for crystallizing solute	Formation of nuclei is delayed and fine, symmetric crystals are produced Interaction of certain functional groups between solvent and solute may impede growth at selected crystal faces Requires a high ratio of crystallizing solute/crystallizing solvent for producing well-defined shaped crystals	Desired crystal size with better dissolution and flowability Elongated crystals may be produced that are suitable for formulations because of their better flowability and sedimentation behavior
2. Less affinity for crystallizing solute	Nuclei are formed immediately and crystal growth is rapid; relatively larger crystals are produced A low ratio of crystallizing solute/crystallizing solvent is required for obtaining well-defined shaped crystals	
<i>Temperature of crystallizing solvent</i>		
1. Low temperature	Rapid nuclei formation because of spontaneous decrease in saturation level produces irregular shaped crystals	Irregular (dendritic) shaped crystals are not suitable for tableting
2. High temperature	Nuclei formation is delayed and fine, symmetric crystals are produced	Desirable shape and size of crystals can be obtained that are suitable for dosage forms
<i>Presence of impurities</i>		
1. Adsorbable ions, solute molecules	Inhibition or excessive growth of certain crystal faces	Desirable crystal morphology can be obtained during purification by recrystallization
2. Structural compatibility between polymer and drug	Interaction of functional groups between polymer and crystallizing solute restricts growth at certain crystal faces	Prevention of habit transformation

^aNo generalization can be made with regard to influence of process variables of crystallization on crystal habit and dosage form performance because the influence of a process variable is interactive and not independent of the other variable. The influences listed here should be used as a guideline only. (From Ref. [72], p. 701, by courtesy of Marcel Dekker, Inc.)

the crystal formation was a fourth-power step. The precipitation was found to be diffusion-controlled when the concentration was greater than 0.4 mM and could be characterized by the equation:

$$K_0 t = \int_0^a a^{-1/3} (1-a)^{-1} da$$

When the concentration was less than 0.4 mM, the kinetics could be described by the equation:

$$K_R t = \int_0^a a^{-2/3} (1-a)^{-4} da$$

where a represents the degree of precipitation. Hence an initial concentration less than 0.5 mM produced small prismatic crystals, and a concentration between 0.5 and 1.5 mM produced distorted prisms (corners grew more than the middle of the faces). However, at concentrations greater than 1.5 mM, the corners grew much more than other parts of the crystal, giving them a star-shaped appearance. It has been suggested that star-shaped crystals should be produced when the growth of crystals is diffusion-controlled because the concentration of crystallizing solute shall be greatest at the corners. On the other hand, rectangular-shaped crystals can be envisaged when the concentration of depositing solute is the same over the entire surface. This takes place when the rate of consumption of the solute is slower than the rate of diffusion.

Crystals of anhydrous cholesterol obtained from ethanol under quiescent conditions with a low supersaturation value were platelike; those obtained from shaken solutions were elongated, and those precipitated from stirred solutions were needlelike. The same trend was observed when acetonitrile or methanol was used as crystallizing solvents.^[8] Formation of needlelike crystals at high supersaturation of less polar solvent can be attributed to the significant solvent-solute interaction. Significant interaction probably results in preferential blocking of some faces, forcing the crystals to grow in one direction, resulting in a needlelike habit. Similarly, platy crystals are formed when the solute-solvent interaction is less.

Solute-solvent interaction is reported to influence the habit of stearic acid.^[9] It is worth noting that the addition of small amounts of surfactants forces stearic acid crystals to grow only in one habit modification regardless of the nature of solvent and the crystallization conditions. This is because of the modification of solute-solvent interaction by added surfactant molecules. Therefore in the absence of significant solute-solvent interaction (using relatively inert solvents), the degree of supersaturation will perhaps predominantly govern crystal habit. Supersaturation also influences the particle size of crystallizing solute. At high supersaturation, nucleation is more rapid than growth.

This results in the precipitation of fine particles. In thermal recrystallization, however, large crystals are produced because growth is faster than nucleation.^[10]

The degree of saturation in diffusional boundary layer next to the predominant face of a growing crystal can alter crystal growth in unstirred systems. Such a stagnant boundary layer that may be as thick as 150 μM can restrict diffusion and deposition of crystallizing molecules on growing crystal faces. Adsorbed impurities/polymers shall further retard crystal growth.^[11] Therefore the state of supersaturation of mother liquor appears to alter the shape of crystallizing particles by influencing the uniform deposition of molecules at different faces. It is important to note that the state of supersaturation depends not only on the choice of solvents used for solubilizing the drug, but also on the characteristics of the selected crystallizing solvent. The combined influence of both these solvents is critical in modifying habit as well as size of the crystallizing particles.

Rate of Cooling and Degree of Solution Agitation

Rate of cooling modifies crystal habit through its influence on the degree of supersaturation in mother liquor. Cooling a supersaturated solution of a drug or pouring it into crystallizing solvent maintained at low temperature immediately decreases the drug's solubility and results in rapid deposition of drug molecules on the nuclei.

Rapid cooling of a solution of naphthalene in ethanol or methanol produces thin plates, whereas slow cooling produces compact crystals. This is because of slow deposition of drug molecules on crystal faces at low rate of cooling.^[12] It has been suggested that rapid cooling usually produces needle-shaped crystals because an elongated shape is most efficient in dissipating heat.^[13] When the rate of cooling is decreased, the solution is maintained below saturation for longer duration. This results in delayed nuclei formation, slow deposition of crystallizing molecules, and, eventually, appearance of symmetric crystals. Slow cooling of a solution of acetazolamide in boiling water produced elongated prisms while faster cooling produced platy crystals.^[14] Similarly, cooling an aqueous saturated solution of paracetamol from 65°C to 25°C produced polyhedral crystals. However, when concentrated solution in hot ethanol is added to water (3°C), platy crystals were obtained.^[14] Hence modulation of the rate of cooling during crystallization could be employed as an effective means to alter crystal habit. As a corollary, habit changes shall be inevitable when a dosage form is repeatedly subjected to changes in temperature during processing or storage where the drug particles shall dissolve and then recrystallize to produce new crystals.

The degree of solution agitation is logically expected to influence saturation level at solid–solvent interface of the nuclei as well as bring about temperature drop in the system. This is probably the reason for the formation of large platy crystals from quiescent solutions and elongated crystals from stirred solutions.^[8] The effect of rate of solution agitation does not seem to have been studied extensively and needs critical evaluation.

Nature of Co-Solvent and Crystallizing Solvent

Crystallizing solvent is the medium into which a saturated drug solution prepared in a co-solvent is added to effect crystallization by precipitation. They may be a buffer (pH change method), water, or an organic solvent. As a prerequisite of this process of crystallization, the crystallizing solvent should be miscible with the liquid in which saturated solution of drug has been prepared. This requirement of miscibility implies that the intensity of solute–solvent interaction can be modified by selecting different co-solvents and/or crystallizing solvents.

Cholesterol is reported to crystallize as needles from ethanol and methanol and as platy crystals from acetonitrile.^[8] Trimethoprim^[16] and sulfamethoxazole^[17] have been crystallized in distinctively different habits from different crystallizing solvents (Fig. 2). These studies also

revealed that it was possible to obtain different habits of either drug belonging to the same polymorphic state using the same crystallizing solvent by just altering the process variables of crystallization such as co-solvent/crystallizing solvent ratio, temperature of co-solvent and crystallizing solvent, and rate of cooling. Co-solvents having high affinity for either drug required a higher ratio of co-solvent to crystallizing solvent for producing a well-defined morphology. A decrease in the initial supersaturation as a result of the elevated temperature of co-solvent or crystallizing solvent delayed the onset of nuclei formation and crystallization, thereby producing small crystals with equidimensional morphology. This was suggested to be a result of the slow and uniform deposition of solute molecules on the nuclei. However, variation of cooling rate did not appreciably affect the habit because of spontaneous precipitation of the drug. Therefore these studies suggest that process variables are as important as crystallizing solvent in modifying crystal habit and should be paid due attention while preparing crystals with specific attributes.

The interaction of a crystallizing solvent at various crystal–solution interfaces may lead to altered roundness of the growing crystal face/edges, change in crystal growth kinetics, and enhancement or inhibition of growth at certain crystal faces thus changing the habit.^[18] In addition, polarity of the solvent and its preferential adsorption at selected crystal faces can significantly alter

Fig. 2 Photomicrographs (magnification 200 \times) showing different habits of sulfamethoxazole (A and B same polymorph) and trimethoprim (C and D same polymorph): A and C—commercial drug samples; B—obtained by dissolving sulfamethoxazole in PEG 200 at room temperature and adding to water (70°C) in a ratio 1:20 followed by cooling at 4°C; D—obtained by dissolving trimethoprim in dimethyl formamide at room temperature and adding to water (70°C) in ratio 1:20 followed by cooling at room temperature.

Fig. 3 SEM micrographs of commercial sodium diclofenac (anhydrous) (A); precipitated in tetrahydrate form (B); potassium diclofenac (dihydrate) (C); potassium diclofenac dihydrate (dehydrated at 100°C) (D); sodium diclofenac crystallized from methanol (E); potassium diclofenac crystallized from methanol (F). (From Ref. [20]. Reproduced with permission of John Wiley & Sons, Inc.)

the properties of crystallized solid particles. Nitrofurantoin has been reported to form a monohydrate when crystallized from formic acid/water (2:1) mixture because of the greater interaction of its polar regions with water than with formic acid. These water molecules have been sug-

gested to be retained at the active sites during crystal growth, while desolvation of formic acid occurs more readily thereby producing an altered habit.^[19]

Diclofenac sodium when dissolved in hot water and kept overnight crystallized in tetrahydrate form, whereas

its potassium salt crystallized in dihydrate form. Fig. 3A shows that the commercial sodium diclofenac existed as sturdy opaque crystals. Thin leaflet-shaped crystals were obtained when it was precipitated from water (Fig. 3B). On the other hand, potassium salt was found to exhibit a regular bladed morphology (Fig. 3C) that was lost after dehydration at 100°C (Fig. 3D). Recrystallization of sodium and potassium diclofenac from methanol produced stratified (Fig. 3E) and thin elongated rod-shaped crystals (Fig. 3F), respectively.^[20] Similarly, recrystallization of sulfadiazine from ammonia solution produced long, prismatic, smooth-edged crystals with markedly different physicochemical properties.^[21]

The nature of solvent has been found to have a profound effect on crystal habit of ibuprofen. Ibuprofen crystals precipitated from ethanol and acetone (solvents having high surface tension, dielectric constant, and less specific gravity) were thin, platy, and nearly circular-shaped, whereas those obtained from propylene glycol and 2-propanol were rod-shaped.^[22] Similar observations have been reported by Garekani et al.^[23] where all the habits of crystallized ibuprofen particles belonged to a common polymorphic state. Circular or polyhedral habits of ibu-

profen obtained by precipitation from polar solvents can be ascribed to the insignificant interaction with these solvents. Significant interaction in sodium hydroxide (pH 10) solution resulted in the precipitation of needle-shaped crystals when the pH was decreased by the addition of hydrochloric acid. However, spherical agglomerates were obtained when ibuprofen was dissolved in acetonitrile because of its limited miscibility with water in which crystallization occurred on emulsion droplets (Fig. 4).^[24]

It is important to note that unlike in precipitation method, both polar solvent, such as acetone, and nonpolar solvents, such as diethyl ether and hexane, produced needlelike crystals of ibuprofen when saturated solutions were cooled to 5°C over 120 min. Dichloromethane produced cubic, whereas acetonitrile produced spherical agglomerated crystals by this method. Solvent evaporation of ethanol gave platy crystals and diethyl ether gave needle-shaped crystals.^[24] The ability of a solvent to crystallize ibuprofen into strikingly different habits without changing its polymorphic state can be suggested to be a result of the alteration of solvent-solute interaction brought about by the use of different crystallization methods. Ibuprofen dissolves to a greater extent in semipolar

Fig. 4 SEM micrographs of ibuprofen commercial sample (A); crystals prepared by solvent change method using isopropyl alcohol (B); sodium hydroxide (C); acetonitrile (D). (From Ref. [24], p. 1083, by courtesy of Marcel Dekker, Inc.)

and nonpolar solvents, indicating a very high solute-solvent interaction. When crystallization is performed by precipitation in water, this strong interaction is weakened very soon and the crystal growth is not inhibited. This results in the deposition of solute molecules on all faces of the nuclei thus producing platy, polyhedral, or circular-shaped crystals. However, when crystallization is performed by temperature reduction or evaporation, the initially strong interaction is maintained till the end of the process. Therefore nuclei growth is inhibited on certain faces to the extent that both semipolar and nonpolar solvents produce needle-shaped crystals.

Presence of Impurities

Ions, polymeric molecules, or other substances present in solute or solvent can act as impurities for the growing crystals. Surface adsorption of methylated spirit on manitol seed crystals has been reported to produce highly porous surfaced crystals that were more resistant to vibrational segregation.^[25] At the molecular level, impurities may get adsorbed in crystal lattice and disturb the regular and repeating arrangements of a crystal. Such defects give rise to local regions of molecular disorder relative to the original crystal structure and are said to be in an activated state because of the greater molecular mobility and exposure of more reactive chemical groups. Hence such defects in the crystals lead to enhanced reactivity, solubility, and dissolution. Detailed discussion on such crystal lattice defects that lead to alteration in polymorphic state is not within the scope of this topic. However, because of their importance in influencing stability, dissolution, solubility,^[26,27] and thereby biological performance, it is necessary to ensure the absence of polymorphic modifications as a result of the crystal lattice defects to clearly define the role of crystal habit.

It will be more pertinent here to understand the mechanisms by which lattice defects created by added impurities modify crystal habit. Whetstone^[28-30] suggested that habit modification of inorganic salts depended on the anionic and cationic substitution and on the nature of substitution present in dyes. At low saturation level, an increase in the impurity concentration (cationic or anionic surfactants) was found to result in cessation of growth at certain crystal faces, whereas at high saturation, these surfactants produced less effect on the habit of adipic acid. Furthermore, anionic and cationic surfactants as impurities were found to modify the habit to needles and flakes, respectively.^[31,32] When valeric or undecanoic acid were added as impurities, adipic acid crystallized as cigar-shaped spars with rounded edges. Further increase in the concentration of impurities produced fused pairs of spherules. A linear plot of the maxi-

Fig. 5 Schematic illustration of growth process that produces dumbbell-shaped crystals of adipic acid. (From Ref. [36]. Reproduced with permission of John Wiley & Sons, Inc.)

mum growth rate slope of desupersaturation of adipic acid against concentration of caproic acid (impurity) suggested that its selective adsorption on various faces except near the surface was responsible for habit modification of adipic acid.^[33] Earlier, dumbbell-shaped appearance of modified crystals of adipic acid was suggested to arise from crystallographic twinning because of the similarity of the *a*- and *c*-axes of the unit cell.^[34] These crystals have been reported to possess modified density, crystal energy, and dissolution rate.^[35] Recently, it has been found that decanoic acid gets incorporated into adipic acid crystal {102} surface that results in loss of facets in the {010} zone. These lattice distortions result in crystals having misaligned domains, but they are not crystallographically twinned.^[36] Fig. 5 summarizes the steps that lead to the final dumbbell or “figure-of-eight” shaped morphology of adipic acid.

Apart from dyes and surfactants, polymeric molecules also influence the crystal habit of developing crystals. Sulfathiazole has been reported to grow out in finger-like protrusions in the presence of polyvinylpyrrolidone (PVP). It was suggested that PVP formed a “net” over the developing crystals. The effective pore size in the “net” and growth inhibition depended on the relative transport rates of PVP and sulfathiazole to crystal surface.^[37] Carbamazepine (anhydrous) is known to convert to the dihydrate form in water,^[38] and the growth of these crystals occurs by whisker mechanism. Both hydroxypropylmethyl cellulose (HPMC) and egg albumin (EA) have been found to retard the conversion of anhydrous carbamazepine to the dihydrate form in a concentration-dependent manner. In addition, HPMC was found to prevent the crystallization of the α -form. These preventive effects of HPMC at low concentrations could not be explained by simple adsorption because the polymer chain remained entangled and less mobile to enwrap all growing sites effectively. Therefore it was proposed that HPMC served as a template for heterogeneous nucleation, to which carbamazepine dimer attached through hydrogen bonding. More specifically, structural matching between interatomic distances

in the crystal lattice and intra-atomic distances along the polymer chain can be envisaged to be responsible for transformation inhibition.^[39] On the other hand, with EA, the prevention of crystallization of α -form was found to be less pronounced because of its lower ability to form hydrogen bonds with carbamazepine molecules. Egg albumin was found to decrease the degree of carbamazepine conversion to dihydrate form and whisker growth through an increase in aggregation of its dihydrate crystals. An increase in contact angle after addition of EA and reversibility of EA effect on aggregation by sodium dodecyl sulfate suggested that EA prevented the crystal growth of carbamazepine by increasing the dihydrate–liquid interfacial tension. Additionally, EA served as a microsubstitute for nucleation, thereby enhancing the two-dimensional nucleation on whisker sides.^[40]

It is interesting to note that PVP that contained only one hydrogen bonding carbonyl group per monomer unit was ineffective even at 500 times higher molar concentration than the minimum concentration of HPMC required to completely inhibit the transformation of carbamazepine to its dihydrate form.^[40] In contrast, crystal habit of paracetamol was found to be effectively modified by PVP with higher influence being exerted by higher molecular weight derivatives (PVP 10 000 or 50 000). Adsorption of high molecular weight PVP onto paracetamol growing crystals resulted in nearly spherical structure consisting of numerous rod-shaped microcrystals agglomerated together without any change in polymorphic state.^[41]

Discrepancies regarding the influence of polymeric impurities on habit modification seem to be because of the complex nature of nuclei formation and growth during crystallization. Polymers can get incorporated into the crystal only when they are similar to the crystallizing molecule in size or structure, which is often not the case. Hydroxypropylmethyl cellulose has been found to act as both growth inhibitor and habit modifier of hydrocortisone acetate, whereas PVP and polyethylene glycol 400 acted predominantly as growth inhibitors. This was suggested to be a result of the stronger interaction of HPMC (via hydroxyl groups) at the surface of the growing crystal. The influence becomes more pronounced in unstirred systems where a diffusional boundary layer adjacent to the growing crystal surface is formed. The accumulation of polymer molecules in this layer provides resistance for drug molecules to diffuse through and leads to growth inhibition. Additionally, habit gets modified when the polymeric groups get preferentially adsorbed at particular crystal faces thereby preventing growth of these faces, while other faces grow normally. Polymers that do not interact and get just adsorbed therefore lack the ability to modify the habit.^[11]

Polymorphic molecules such as methacrylic co-polymers may modify crystal habit by virtue of their ability to

form micelles because of the presence of quaternary ammonium groups in their molecules. Water-insoluble eudragits (RS and RL) that increased the solubility of ibuprofen produced more reduction in crystal yield than the water-soluble eudragits (L and S). However, all these polymers produced agglomerated spherical crystals with rough surfaces that were exhibited increased porosity. Greater pore diameter in crystals precipitated in the presence of eudragits accompanied with increased intraparticle porosity suggested the absence of polymer deposition in the empty spaces between microcrystals in the agglomerates.^[42]

Tailor-made impurities can be used for specific drug molecules. The use of *p*-acetoxyacetanilide (PAA) during crystallization of paracetamol has been found to produce columnar crystals. The incorporation of PAA into critical nucleus delayed the onset of nucleation and resulted in crystals that exhibited significant mosaic spread, implying the development of significant strain/defect content in the crystals.^[43]

Therefore irrespective of the mechanism under operation, the addition of impurities during crystallization can be advantageously employed to engineer crystal habit if the impurity is known to modify the growing crystal into a morphology that is desirable from the viewpoint of dosage form design and performance.

SIGNIFICANCE OF CRYSTAL HABIT IN DOSAGE FORM PERFORMANCE

Tablet Formulation

It is well known that crystal habits exhibiting symmetric morphological characteristics such as the cubic system present no difficulty during direct compression into tablets. Jaffe and Foss^[44] pointed out that binary compounds are found predominantly in the cubic and hexagonal system and are characterized by higher symmetry than ternary and more complex compounds found in the rhombic, monoclinic, and triclinic systems. Low-symmetry structures such as carbonates of calcium, lead, nickel, potassium, silver, and sodium have been reported not to form tablets on direct compression. The regular spherical particles of spray-dried lactose form stronger tablets compared with angular particles on direct compression.^[45] Similarly, replacement of platy habit (form B) by nonplaty (form A) crystals of tolbutamide has been reported to obliterate capping of tablets.^[46] These findings suggest symmetry of crystals to be a prerequisite for direct compression.

Successful tableting requires uniform flow from the hopper, proper packing, rearrangement, reduction in porosity, and deformation of particles in the die cavity. Flat

needle-shaped crystals of aspirin have been found to align themselves parallel to the punch face, forming a layered structure that exhibited low lateral stress transmission characteristics.^[47] An increased radially transmitted stress with flaky powered material^[48] reinforces this contention. Apart from the mechanical influence of crystal shape, another dominant factor that results from the anisotropy of cohesion and hardness (of low-symmetry crystals) also contributes to the ease of compression. As crystal habit varies, the dominant faces vary in relation to this anisotropy and tend to orient the crystals during compaction process thus exhibiting great differences in packing and compression kinetics.

Cubic sodium chloride crystals that pack in a bricklike fashion have been found to exhibit greater density than the dendritic crystals. In addition, reduced slip between dendritic crystals made rearrangement difficult and resulted in greater loss of compaction force to the die wall.^[49] Ibuprofen is generally crystallized industrially from hexane in the form of elongated needlelike crystals. This shape has been found to be unsuitable for tableting because of the poor flow properties. Equidimensional crystals obtained using methanol have been reported to possess better compaction features and flow properties.^[23,50] Crystal morphology of excipients such as powdered cellulose^[51] and calcium alumina trihydrate^[52] has also been reported to significantly influence strength, content uniformity, and disintegration time of tablets.

The platelike nitrofurantoin crystals are reported to undergo greater densification and plastic deformation than the needlelike crystals. Furthermore, tablets prepared from needlelike crystals exhibited a higher degree of axial recovery after ejection. This was suggested to be a result of the development of larger nonpolar faces in platelike crystals that were crystallized from formic acid than polar faces of needlelike crystals crystallized from formic acid/water mixture. The relative abundance of these faces probably affected the magnitude and the strength of bonding during compression.^[53]

An orthorhombic structure is characterized by high molecular density and weak interplane bonds. During the initial stages of compression cycle, these planes have been suggested to act as slide planes giving rise to substantial interparticle rearrangement, thus resulting in volume reduction. At high pressures, these crystals undergo plastic deformation with low elastic recovery as compared with monoclinic form, thus increasing the points of contact in the compact. Because of these reasons, orthorhombic paracetamol crystals exhibited good tablet forming property with no tendency of capping.^[54] Platy crystals of paracetamol have been reported to exhibit lower correlation coefficient values for Heckel plots and strain rate sensitivity, indicating greater fragmentation compared with polyhedral crystals. Tablets compressed from platy crystals

showed higher elastic recovery, suggesting that these crystals underwent less plastic deformation.^[15] It has been suggested on the basis of molecular geometry of paracetamol crystal lattice that the cleavage along the {010} plane follows a serrated path and the interplanar bonding is of van der Waals type. However, along both {110} and {210} planes, cleavage requires breakage of two hydrogen bonds per unit cell. In addition, the lowest attachment energy and maximum slice energy for the {010} plane strongly suggested that the fracture in paracetamol crystals occurred along the {010} crystal plane.^[55,56]

Compression of particles may alter the internal structure as well as their morphology. These changes are opposed by intermolecular forces that restore the crystal to its original form and results in elastic recovery. If the intermolecular forces are exceeded, then plastic flow occurs. It has been suggested for aspirin that the displacement occurring along the slip planes inside the crystal moved in an orderly manner to a new location, with the molecular packing arrangement remaining unchanged. However, cubic sodium chloride crystals possess numerous potential slip planes for plastic deformation, and microscopic examination did not reveal shearing effects. This indicates that shearing occurred at the molecular level in cubic sodium chloride crystals.^[57] An increase in compression pressure decreased the crystallinity of lactose, producing stronger tablets as a result of the more activated crystals dissipating acquired energy by interparticle bonding.^[58] Compacts made from equidimensional crystals of L-lysine monohydrochloride dihydrate in the absence of excessive pressure showed wider flaws (wider cracks between particles), whereas those from long rod-shaped crystals had longer flaws. These compacts of rod-shaped crystals were found to have poor strength probably because of the higher stress intensity at the crack tip that propagated to longer distances along the interparticle boundary.^[59] In addition, variation in the degree of surface crystallinity has been found to exhibit enormous influence on tablet properties.^[60] Hence an equidimensional habit that undergoes the highest degree of densification and exhibits a tendency to form new bonds at the fragmentation sites during compaction seems to offer great advantage for tablet formulation.

Dissolution

Dissolution of a drug depends on the physicochemical and physicochemical properties of drug particles. These crystal attributes directly affect the absorption kinetics of a drug and thereby bioavailability of dosage forms. This assumes greater importance for drugs exhibiting low solubility that makes absorption to be dissolution rate-limited. It is established that an increase in solubility can be brought by modifying the polymorphic state of a

compound. But the influence on other attributes such as stability, biological efficacy, metabolism, etc. as a result of change in polymorphic state demands a thorough investigation while using this approach. Modifying surface morphology of crystals without altering the polymorphic state seems to offer an attractive alternative approach for enhancing the dissolution of drugs. Furthermore, it is necessary to standardize the surface characteristics for minimizing differences in dissolution behavior of drug particles obtained from different batches/sources.

The size and the number of crystal faces exposed to solvent attack determine the amount of drug dissolved. It was shown that the lifetime of potassium ferricyanide crystal was proportional to the smallest length of the crystal face in contact with liquid paraffin–water interface. Furthermore, nonisometric dissolution of the crystal face indicated a change in crystal shape during dissolution.^[61] The shape factor of a single crystal of potassium dichromate changed significantly after 50% dissolution and was dependent on the degree of nonisometricity of the crystal.^[62] These reports indicate that a continuously changing dissolution profile can be anticipated for certain habits such as rods and needles because of the more solvent attack on predominant faces of the crystals as dissolution progresses.

At the molecular level, dissolution can be visualized to involve interaction of solvent with functional groups in the drug particles. Additives/impurities present in drug particles may alter the intensity of drug-dissolution medium interaction thereby modifying dissolution characteristics. Hydroxypropyl β -cyclodextrin has been found to be more effective than PVP in inhibiting the crystal growth and enhancing the dissolution of nifedipine.^[63] However, additives may sometimes even reduce the dissolution rate. A combination of Eudragit RS and cellulose acetate phthalate has been shown to alter the habit and sustain the release of an iron chelator.^[64] Crystallization of sulfadiazine from ammonia solution significantly decreased the dissolution rate because of the reduced wettability of the outer surface of recrystallized particles that seems to arise from the influence of crystallizing liquid.^[21] Depending on the solvent used for crystallization, internalization of the functional groups that are less attracted to the liquid takes place. Similarly, reduced wettability associated with agglomeration of crystals has been proposed to decrease the dissolution of ibuprofen crystals recrystallized from acetonitrile or methanol.^[24] It is important to note that nonionic impurities such as Tween 80 that do not disturb the arrangement of sulfadiazine molecules in ammonia solution did not appreciably affect the dissolution of recrystallized sulfadiazine. On the other hand, although the addition of sodium chloride as an impurity did not increase wettability, the dissolution of crystals was enhanced. It has

been proposed that probably sodium chloride, as a result of its ionic nature, reduced the interaction of ammonia with sulfadiazine through ion–dipole interaction. This in turn resulted in reducing the effect of ammonia on orientation of functional groups present in sulfadiazine molecules during recrystallization, thereby negating the dissolution retarding influence of ammonia on recrystallized sulfadiazine crystals.^[21]

The literature abounds with reports of investigations on enhancement of dissolution of drugs having low aqueous solubility by change in crystal habit. Ibuprofen crystals prepared by precipitation from ethanol and acetone have been reported to exhibit enhanced dissolution than the rod-like crystals obtained from propylene glycol and 2-propanol.^[22] Preparation of ibuprofen crystals by using phase partition technique and employing Tween 80 in the binding solvent have been found to produce microcrystals which when compressed into tablets exhibited dissolution comparable to that of commercial product with respect to USP 24 requirement ($Q > \text{or} = 80\%$ at 60 min).^[65] Other drugs that are known to have low aqueous solubility such as aspirin,^[66] mefenamic acid,^[67] and etoposide^[68] have also been reported to exhibit better dissolution after modification of crystal habit. However, results of dissolution enhancement should be cautiously interpreted because most studies do not often aim at delineating the role of crystal habit from that of polymorphic state which usually accompanies recrystallization of drug particles.

A pharmaceutical sample usually contains a mixture of habits. This is because of the complex natures of crystallization process in which even a scratch in the container or presence of dust particles is capable of initiating nuclei formation and modifying habit of growing crystals. Because of these mixed habits, the dissolution profile cannot be ascribed to a particular habit unless this shape constitutes a significant proportion of the bulk. Hence to correctly characterize the dissolution behavior and evaluate the contribution of various crystal faces, studies are made on single crystals. Prasad et al.^[69] have reported that the dissolution rate of {001} and {110} faces of paracetamol crystals grown in the presence of molecularly similar additive *p*-acetoxyacetanilide were higher than that of pure paracetamol. This was attributed to the distribution of strain in the crystal that increased its solubility.^[69] Apart from inclusion of impurities, processing variations can also lead to development of such strains. Moisture taken up even in low amounts in these areas of “strain” or “disorder” can plasticize the solid and promote molecular mobility that results in enhanced dissolution, chemical degradation, and solid-state changes such as recrystallization.^[26,27]

It is noteworthy that modified habits of trimethoprim and sulfamethoxazole having different habits but

belonging to the same sieve fraction and polymorphic state exhibited significantly different dissolution profiles. For both drugs, symmetric crystals were found to dissolve faster probably because of the uniform exposure of all the surfaces to dissolution medium. However, symmetric crystals having a higher size factor (length \times breadth) exhibited slow dissolution during the early phase. But during the later phase, as the size factor decreased, the dissolution rate of these crystals was found to increase. Symmetrical crystals that possessed low zeta potential exhibited considerable aggregation and dissolved slowly.^[16,17] It is perhaps for the first time that change in crystal habit has been shown to be associated with alteration of surface charge. The fact that surface charge has an ability to influence not just the aggregation state but also other powder characteristics such as mixing, flowability, dissolution, and solubility, it seems logical to evaluate the electrophoretic motility of recrystallized particles. Nevertheless, altering crystal habit seems to offer an approach for modifying the dissolution behavior of drugs.

Suspensions

The influence of crystal habit on performance of suspension dosage form can be envisaged to be more pronounced than other dosage forms because of greater space available for reorientation and packing of dispersed particles. Furthermore, selection of a stable habit is essential to avoid crystal growth that leads to physical instability during the shelf life of suspensions.

Investigations on trimethoprim^[16] and sulfamethoxazole^[17] suspensions have revealed that crystals with high shape factor ($1/L \times 1/B$) exhibited high sedimentation volume and could be easily redispersed. It was suggested that during settling, these crystals perhaps formed an end-to-face rather than an end-to-end framework because this would result in decreased free energy of the system. Although these anisometric crystals possessed high zeta potential, they tend to induce "self-flocculation," which produced a scaffold-like, porous pack structure that was less susceptible to overhead pressure of settling particles. On the other hand, crystals with irregular shape exhibited low sedimentation volume and were not easily redispersed because of cake formation. This was because of the reorientation of irregular crystals during sedimentation that lead to close-fit packing. It is noteworthy that a massive increase in sedimentation volume (sixfold) was obtained by employing rod-shaped crystals of trimethoprim in deflocculated suspension.^[16] The pharmacokinetics of both trimethoprim and sulfamethoxazole crystals was not significantly altered as compared with the respective pure drug powders probably because of their reported rapid absorption which does not render their bioavailability to be dependent on dissolution. However, studies on drugs that have inherently low solubility and/or low intestinal permeability are advocated to test the validity of this hypothesis.

It is important to consider the influence of interaction between functional groups of drugs that leads to their habit modification when formulated in suspension dosage form. Proton transfer from the N atom of sulfamethoxazole

Fig. 6 Photomicrographs (magnification 200 \times) of crystals showing modified habit produced after interaction between aqueous dispersions of sulfamethoxazole and trimethoprim: molar ratio 5.73:1 (A); molar ratio 1:1 (B); HPMC added before mixing aqueous dispersions (C); HPMC added after mixing aqueous dispersions (D).

to the pyrimidine basic N1 atom of trimethoprim has been reported to occur in their equimolar complexes.^[70] Bettinetti et al.^[71] have reported nucleation of the complex of trimethoprim and sulfamethoxypyridazine (1:1) to be accelerated by water or wet granulation. Our studies on cotrimoxazole (unpublished results) revealed immediate formation of fine needle-shaped crystals irrespective of the initial shape of sulfamethoxazole and trimethoprim crystals as a result of the interaction between the two drugs in suspension form. Small needles (Fig. 6A) were produced when the aqueous dispersions of both drugs were mixed in amounts that are normally present in pharmaceutical suspensions (molar ratio sulfamethoxazole/trimethoprim: 5.73:1). Using the same processing conditions, long needle-shaped crystals were produced when the molar ratio was 3:2, 1:1, 2:3, or 1:2 (Fig. 6B), and these dispersions exhibited a sedimentation volume of 1.00 after storage over 2 months at 35°C. Furthermore, addition of aluminum chloride as flocculating agent modified the original crystals to long needle-shaped crystals. This was also evident when aluminum chloride was added to aqueous dispersion of trimethoprim. Addition of HMPc (1% w/v) before mixing dispersions of both drugs did not allow complete interaction as a result of which formation of needle-shaped crystals was found to be incomplete (Fig. 6C) and the resultant dispersions exhibited caking after storage. Perfect needles were formed but possessed shorter length (Fig. 6D) when HPMc was added after mixing the dispersions of both drugs. The results of these investigations strongly indicated that habit modification can result from interaction between functional groups in physical mixtures of drugs and that the intensity of modification can be altered by the formulation and processing variables. This influences the stability of suspension dosage forms, and hence occurrence of such habit modifications should be given due attention during preformulation. As a corollary, this approach could be used to enhance the physical stability of drug suspensions that are prone to caking on storage. This can be achieved by employing interaction between the drug and an inert substance to produce crystals with appropriate habit that can form a porous pack structure that will embed the drug particles. Such suspensions shall exhibit high sedimentation volume and ease of redispersibility. However, feasibility of using this approach is yet to be tested.

CONCLUSION

Crystal morphology is an important attribute of solids. Both crystal shape (habit) and surface appearance can be significantly altered by the process variables of crystal-

lization. Crystallization, which is often used for purifying/recrystallizing a drug powder, may modify either polymorphic state, crystal habit, or both. Although seemingly trivial, crystal habit plays a significant role in influencing packing, flowability, compressibility, dissolution, and sedimentation characteristics of pharmaceutical powders. Therefore selecting a stable polymorph may not alone solve the problem if the polymorph exists in distinctly different habits that can modify the physical stability of the dosage form. In addition, polymorphic transformations or crystal growth during storage may accompany change in crystal habit. Furthermore, development of strain in crystal lattice either because of impurities/additives or during processing can lead to changes in habit that can alter the performance of dosage form. Hence it is imperative to study changes in crystal habit along with changes in polymorphic state at critical processing stages. This shall help in maintaining uniformity in raw material characteristics and batch-to-batch dosage form performance besides formulating a stable dosage form with required performance.

COSOLVENTS AND COSOLVENCY

Joseph T. Rubino

Wyeth-Ayerst Research, Pearl River, New York, U.S.A.

INTRODUCTION

Cosolvents are defined as water-miscible organic solvents that are used in liquid drug formulations to increase the solubility of poorly water-soluble substances or to enhance the chemical stability of a drug. Cosolvency, then, refers to the technique of using cosolvents for the stated purposes; it is also commonly referred to as solvent blending. Cosolvency has been used as an approach for preparing liquid drug preparations throughout the history of drug formulation. Certain drugs of botanic origin were known to be poorly soluble in water and required formulation in water-ethanol mixtures in order to deliver an adequate dose of drug in a small volume of preparation. A common example of a class of formulation containing cosolvents is the elixir, which by definition is a sweetened, hydroalcoholic solution intended for oral use. Tinctures, which generally contain even higher amounts of alcohol, are another classic example of a liquid dosage form containing a cosolvent. The need to employ cosolvents in the formulation of new drugs as solutions for oral, parenteral, and topical use remains high, especially with the increasing structural complexity of new therapeutic agents.

In many cases, cosolvency can increase the solubility of a nonpolar drug up to several orders of magnitude above the aqueous solubility. This would be significant, for example, in a formulation problem where it might be necessary to increase the solubility of a drug 500-fold or more. The use of cosolvents to prepare solution formulations of nonpolar drugs is a simple and potentially effective way to achieve high concentrations of drug.

The primary disadvantages of cosolvency include the potential for biological effects and the potential for drugs that have been solubilized using cosolvents to precipitate upon dilution with aqueous fluids. The biological effects of a cosolvent that may limit or eliminate its use in drug formulations include their general toxicity, target organ toxicity, tissue irritation, or tonicity with respect to biologic membranes. In addition, precipitation of drug upon dilution with aqueous media or during injection or application to mucous membranes must always be considered in deciding if a cosolvent can be used as a vehicle for poorly water-soluble drugs. Other considerations

include the viscosity, tonicity, and taste, as well as the effect of cosolvents on the solubility and stability of formulation components other than the drug.

When used as a method for increasing the chemical stability of a drug, cosolvents may be effective by one or two mechanisms. If a drug is susceptible to hydrolytic degradation, cosolvents may reduce the degradation of the drug by substituting for some or all of the water in the formulation. Alternatively, a cosolvent may enhance the stability of a drug by providing a less suitable environment for the transition state of the reactants, provided the transition state is more polar than the reactants themselves (1).

SOLUBILIZATION BY COSOLVENTS

Methods and Theories

Solubility and solvent polarity

The solubility of a solid nonelectrolyte solute in any solvent can be expressed by Eq. 1:

$$\log X = \frac{-\Delta H_f}{2.303RTT_m}(T_m - T) - \log y \quad (1)$$

where X is the solute mole fractional solubility, ΔH_f is the molar heat of fusion, R is the gas constant, T_m is the solute melting point, T is the temperature, and y is the activity coefficient. The activity coefficient is given by Eq. 2.

$$\log y = C_{11} + C_{22} - 2C_{12} \quad (2)$$

where C_{11} represents the cohesive energy of the solvent, C_{22} is the cohesive energy of the solute (drug), and C_{12} is the adhesive energy. Often C_{12} is calculated as some function of both C_{11} and C_{22} . For example, when dispersion forces are involved:

$$C_{12} = (C_{11}C_{22})^{1/2} \quad (3)$$

The larger the value of $\log y$, the lower the solubility of the drug, with the magnitude of y being controlled by the relative magnitudes of the cohesive and adhesive forces. In the case of hydrophobic drug in water, C_{11} will be large

compared to C_{22} and C_{12} . Thus, the solubility will be low due to the large cohesive energy of water and the low energy of interaction with the drug.

In an ideal solution, all intermolecular forces are equal:

$$C_{11} = C_{22} = C_{12}$$

and $\log \gamma = 0$. Although pharmaceutical solutions are rarely ideal, the goal of cosolvency is to make the solution closer to ideal by modification of the solvent polarity. Upon replacement of some water with an organic cosolvent, C_{11} becomes closer in value to C_{22} , which results in both factors becoming more similar to C_{12} . The value of $\log \gamma$ is reduced and the solubility increases. The maximum solubility for a solute generally occurs when the solvent–solvent intermolecular forces are equal to solute–solute intermolecular forces. Thus, the expression, “like dissolves like,” can be understood by this analysis. In some cases, strong polar or charge transfer interactions between solute and solvent can result in a greater than ideal solubility due to relatively strong C_{12} values, which results in a negative value for $\log \gamma$, but generally this will not be the case.

For the purpose of estimating the solubility of a solute it is necessary to have some measure of the “polarity” of a solute or a solvent. Based on Eqs. 1 and 2, a useful polarity index should be a measure of a material’s intermolecular forces, C_{11} and C_{22} . Table 1 contains a list of solvents that are typically used in liquid pharmaceutical formulations and three measures of solvent polarity. Each measure of solvent polarity, or polarity index, is based upon a different measure of a material’s property. For example, dielectric constant is a measure of the electrical insulating properties of a solvent, solubility parameter is determined from the molar energy of vaporization, and interfacial tension is a measure of the 2-D cohesive forces at the solvent–oil interface. Because solubility parameter and interfacial tension relate more specifically to cohesive

interactions among molecules, they have been used more frequently in various theories to explain and predict solubility in mixed solvents. Despite the differences in their determination, there is a general agreement in the rank order of the polarity among the various solvents. Thus, water and glycerin are relatively polar compared to ethanol or polyethylene glycol (PEG), regardless of which polarity index is considered. Other measurements of polarity or solvent–solvent intermolecular forces have been developed that measure hydrogen bond donating and accepting ability, such as Taft and Kamlet α and β values (2, 3), and 3-D solubility parameters that estimate dispersion, polar, and hydrogen-bonding forces (4, 5), etc.

It is important to realize that a discussion of solvent polarity is only useful when considered in relation to a particular solute. Thus, for a semipolar solute such as theophylline, pure ethanol might be considered nonpolar, but for a relatively nonpolar solute such as hydrocortisone, ethanol might be considered semipolar. This concept is illustrated in Fig. 1. For “nonpolar” and “polar” solutes, solubility will continually decrease or increase, respectively, as solvent polarity increases. For “semipolar” solutes, solubility reaches a maximum at some intermediate solvent polarity. It should be noted that the reverse argument (i.e., solute polarity should be discussed relative to solvent polarity) is also valid.

Due to the complexity of intermolecular interactions in hydrogen-bonded solutions, such as those used in pharmaceutical applications, no single parameter is capable of quantifying all interactions. Several theories have been developed to estimate drug solubility in cosolvent–water mixtures. The relationships that have resulted from these theories range from relatively simple to complex, depending on the desired accuracy of solubility prediction. Some theories and guidelines for selecting an appropriate solvent are presented in the following section.

Table 1 Cosolvents and polarity indices

Cosolvent	Dielectric constant ^a (ϵ)	Solubility parameter (δ) (cal/cm ³)	Interfacial tension ^b (dynes/cm)
Water	78.5	23.4	45.6
Glycerin	42.5	17.7	32.7
<i>N, N</i> -Dimethylacetamide	37.8	10.8	4.6
Propylene glycol	32.0 (30°C)	12.6	12.4
Ethanol	24.3	12.7	0.5
Polyethylene glycol 400	13.6	11.3	11.7
Dimethylisobutide	—	8.63	4.2

^aAll values determined at 25°C unless stated otherwise.

^bDetermined against liquid paraffin.

Fig. 1 Solubility vs. solvent polarity for polar, semipolar and nonpolar solutes.

Estimation of solvent composition

The most straightforward method for choosing a solvent composition is via trial and error using a list of pharmaceutically acceptable solvents. In many situations, pharmaceutical formulations can be successfully developed in this way due to the relatively limited number of pharmaceutically acceptable solvents. While this empirical approach is most useful to obtain solubility information in neat solvents, it can become cumbersome when blends of various solvents are desired.

An improvement in the purely empirical approach is the use of aligation methods that can be used to reformulate vehicles based on limited experimental formulation or solubility data. Moore (6) reported a method for the reformulation of liquid vehicles using the approximate dielectric constant ϵ of the pure and mixed solvents. For example, suppose through experimentation that a solvent containing 50% ethanol in water is capable of dissolving the required amount of drug. For some applications, it might be desired to reformulate the solution with propylene glycol–water. It is first necessary to calculate the approximate dielectric requirement (ADR) for the 50% ethanolic solution using the dielectric constants of ethanol and water from Table 1.

$$0.50 (78.5) + 0.50(24.3) = 51.4$$

The basic assumption is that any vehicle with a dielectric constant of 51.4 will solubilize a given drug to the same extent. In general, the ADR can be calculated as follows:

$$\text{ADR} = \sum_{i=1}^n \frac{(\% \text{solvent}_i \epsilon_i)}{100}$$

To calculate the amount of propylene glycol and water required for the formulation, alternate aligation can be used:

$$\begin{array}{r} 78.5 \quad 19.4 \\ 51.4 \\ 32.0 \quad \underline{27.1} \\ 46.5 \end{array}$$

Thus, the required %v/v propylene glycol is $(27.1/46.5) \times 100 = 58.3$. Alternatively, the %v/v of the new cosolvent can be solved using an algebraic method involving the solution of simultaneous equations; however, aligation is a simpler method when more than one cosolvent is to be included in the formulation. When a vehicle is to be formulated for the first time, it is necessary to experimentally determine the concentration of some cosolvent necessary to maintain the required concentration of drug in solution. This value can then be used to calculate the ADR and the final vehicle calculated as illustrated previously.

The use of the ADR method may not always provide accurate vehicle compositions for a given solute since intermolecular forces are dependent on structural characteristics of the solvent and solute that are not expressed by ϵ (7, 8). It is possible, and perhaps desirable, to substitute other measures of cosolvent polarity, such as solubility parameter, surface or interfacial tension, etc., for ϵ when blending solvents, although inaccuracies in vehicle predictions will generally continue to exist.

A second, relatively simple method for estimating the solubility of a drug in cosolvent–water mixtures was developed by Yalkowsky et al. (9). This method is based on the observation that an exponential increase in solubility of a nonpolar solute is observed as the volume fraction of cosolvent, f , increases in a cosolvent–water mixture:

$$\log S_m = S_w + \sigma f \quad (4)$$

S_m represents the solubility of drug in cosolvent–water mixture, S_w represents the solubility of the drug in water, and σ is the slope of a plot of $\log S_m$ versus f . This relationship is illustrated in Fig. 2. Eq. (4) is applicable from 0 to 100% cosolvent when a continuous increase or decrease in solubility occurs, i.e., the equation is not applicable for semipolar solutes that reach a maximum solubility between 0 and 100% cosolvent. Thus, for nonpolar or polar solutes, an estimate of the solubility in cosolvent–water mixtures can be obtained from a knowledge of the drug solubility in water and neat cosolvent, plotting these points on a semilog scale at $f = 0$

Fig. 2 Log-linear solubility relationship for a series of alkyl *p*-aminobenzoates in propylene glycol–water. (From Ref. 9.)

and $f = 1.0$, respectively, and interpolating along a straight line connecting these points.

Additional studies indicated that σ can be estimated for a solute in specific cosolvent–water combinations using the solute octanol–water partition coefficient, $\log P$, as an index of solute polarity. Thus, for propylene glycol–water mixtures (10, 11):

$$\begin{aligned}\sigma &= 0.714(\log P) + 0.714n = 382 \\ r^2 &= 0.962 \quad s = 0.325\end{aligned}\quad (5)$$

and for ethanol–water mixtures (12)^a:

$$\begin{aligned}\sigma &= 0.903(C \log P) + 0.402n = 107 \\ r^2 &= 0.955, \quad s = 0.567 \\ \delta_1 &= \sum_{i=1}^n \delta_i f_i\end{aligned}\quad (6^*)$$

These equations illustrate the concept that the slope in Eq. 4 will be greater for a given cosolvent–water mixture the more lipophilic the solute. That is, the increase in solubility relative to water will be greater the larger the value of $\log P$ for the solute. In general, solutes with a $\log P \geq 2$ will behave as nonpolar solutes in most pharmaceutical solvents and will demonstrate a continual increase in S_m with increasing f .

Alternatively, Rubino and Yalkowsky (13) found that σ was a linear function of cosolvent polarity for a given solute. This is illustrated in Fig. 3 for the three lipophilic compounds phenytoin, diazepam, and benzocaine. Thus, knowledge of the solubility of a given drug in water and at least two cosolvents would permit σ to be estimated for other cosolvents by interpolation using an index of the desired cosolvent polarity. These studies permit the use of Eq. 4 as a means to rationally choose or eliminate solvents for formulation studies based on limited experimental solubility data and commonly obtained indexes of solute and solvent polarity.

Eqs. (4–6) provide approximate solubilities and in many cases should be used to serve as aids to organize solvent selection and minimize experimental work. Viable formulations using these relationships will most likely require further refinement through experimental effort. As with the ADR method, not all intermolecular forces can be accounted for by the simple relationships presented in Eqs. (4–6). For example, experimental solubilities frequently exhibit characteristic deviations from the linear relationship predicted by Eq. 4, (14). It must also be remembered that Eqs. (4–6) pertain to nonelectrolytes or the unionized form of weak electrolytes. The behavior of salts and ions cannot be reliably estimated using these relationships.

Williams and Amidon (15–17) investigated a method that introduces estimates of solvent–solvent, and solute–solvent interactions into the basic log-linear expression. In their approach, cosolvent–water interactions are estimated from vapor pressure data of the solvent mixtures. The data are obtained from literature sources, if available, or determined experimentally. Solvent–solute interactions are estimated from experimental solubility data. An

^a $C \log P$ is a calculated value. The $\log P$ values in Eq. 5 were obtained experimentally or from a literature source.

Fig. 3 Relationship between slope σ and solvent polarity, represented by the solvent interfacial tension, for three solutes. A = phenytoin, B = diazepam, C = benzocaine. (From Ref. 13.)

alternate approach, as described by Khossravi and Connors (18), divides the free energy of solubility into crystal, cavity, and solvation components. While the free energy associated with the crystal is estimated from the

solute enthalpy of fusion, the free energy associated with cavity formation is estimated from solvent surface tension data and solute molecular surface area. The solvation component is derived from a model that assumes a series of competitive exchange equilibria between the solute, water, and cosolvent. The equilibrium constants are obtained by a regression analysis of actual solubility data. These methods, previously described, are potentially more accurate in describing solubilities in mixed solvent systems, but require one or more model parameters that are usually specific to a particular solute-solvent system and must be estimated from experimental data.

Additional approaches to understand and predict solubilities in mixed solvents are based on estimation of the activity coefficient, $\log y$, in Eq. 1. Martin and coworkers (19, 20) investigated the use of regular solution theory, as developed by Hildebrand and Scott (21), to predict the solubilities of organic solutes in various solvent mixtures:

$$\log y = \frac{V_2 \phi_1^2}{2.303 RT} (\delta_1 - \delta_2)^2 \quad (7)$$

where V_2 is the molar volume of solute, Φ_1 is the volume fraction of solvent, δ_1 and δ_2 are the solubility parameters of the solvent and solute, respectively. For mixed solvents:

$$\delta_1 = \sum_{i=1}^n \delta_i f_i$$

where f is the volume fraction of solvent i . When $\delta_1 = \delta_2$, $\log y$ will equal 0 and the solution will be ideal. For mixtures of organic solvents, Eq. 7 provided the greatest agreement with experimental solubilities only when the solute and solvent polarities were not very different. In addition, solutions used as pharmaceutical dosage forms are seldom true regular solutions due to the prevalence of strong polar and hydrogen-bonding interactions. Thus, the application of Eq. 7 to pharmaceutical solutions is limited.

In order to account for polar and hydrogen-bonding interactions, the Extended Hildebrand equation was introduced by Martin et al. (22, 23):

$$\log X = \frac{-\Delta H_f}{2.303 RT} \left(\frac{T_m - T}{T_m} \right) - \frac{V_2 \phi_1^2 (\delta_1^2 + \delta_2^2 - 2W)}{2.303 RT} \quad (8)$$

where W is a factor that accounts for stronger solute-solvent interactions, such as hydrogen bonding and dipolar forces. It is determined experimentally for a given solute via regression analysis of the solubility data. Thus, a solubility database must be developed for each solute. In

addition, while solubility parameters can be readily found for various solvents, they must be either determined experimentally or estimated by calculation for a solute.

An alternative method for estimating activity coefficient involves a consideration of interfacial tension between solute and solvent. Amidon et al. (24) reported this method to estimate the solubility of organic solutes in water:

$$\log y = \frac{A_2 \gamma_{12}}{2.303RT} \quad (9)$$

where A_2 is the solute molar surface area and γ_{12} is the solute–solvent interfacial tension.

Yalkowsky et al. (25) developed the approach for mixed solvent systems:

$$\log X_m = \log X_w + \frac{[C(\gamma_{wh} - \gamma_{ch})A_h]f}{2.303 RT} \quad (10)$$

where X_m is the mole fraction solubility in the cosolvent–water mixture, X_w is the mole fraction solubility in water, γ_{wh} and γ_{ch} are the interfacial tensions between solute–water and solute–cosolvent, respectively, A_h is the hydrophobic surface area of the solute, and C is an empirical factor that corrects for the difference between the molecular and macroscopic interfaces (26). The γ terms in this expression are macroscopically determined interfacial tensions between water–tetradecane and cosolvent–tetradecane. C was found to be constant for each solute in different solvent systems and is determined experimentally (26, 27). A_h is determined by a computer program or by group contribution approaches. As predicted by Eq. 10, when the interfacial tension between a solute and solvent is reduced by addition of a cosolvent, the solubility increases relative to pure water. The similarity between Eqs. 4 and 10 can be noted and provides a further theoretical basis for Eq. 4.

The advantage of using interfacial tension as a measure of solute–solvent interactions is that it can be measured for substances whose intermolecular forces are quite different from each other. Thus, it is useful for estimating solubilities for systems that are highly “irregular.” In contrast, regular solution approaches are useful when solute and solvent polarities are similar and the interfacial tensions are immeasurable.

Dilution of Formulations Containing Cosolvents as Solubilizers

Eq. 4 predicts that an exponential increase in solubility of a nonpolar compound occurs as the volume fraction of cosolvent is increased. However, dilution of a cosolvent–solubilized preparation with an aqueous medium, such as

blood or intravenous (IV) infusion fluids, can result in the opposite phenomenon, an exponential decrease in solubility. This must be compared simultaneously to the change in drug concentration upon dilution, which decreases linearly with the degree of dilution. The effect is illustrated graphically in Fig. 4 (11). The straight lines A and B represent the solubility of the drug as a function of cosolvent concentration in two different cosolvent–water systems. The curved lines represent the concentrations of drug at various degrees of dilution. Precipitation would be expected when one of the drug concentration curves crosses a solubility curve. For three concentrations of drug in system A, it can be expected that concentration III will precipitate when it is diluted to the point where approximately 30% cosolvent is present. Formulations I and II, which contain smaller initial concentrations of drug, do not cross the solubility curve A and should be stable upon dilution. Alternatively, formulation of drug in a cosolvent or solvent mixture that produces a larger slope

Fig. 4 Illustration of the effect of dilution of cosolvent-solubilized formulations with an aqueous medium. (See text for explanation.)

Table 2 LD 50 data for various cosolvents in mice and rats

Cosolvent	LD 50(mg/kg)					
	Mouse			Cat		
	Oral	IV	IP	Oral	IV	IP
Ethanol	7800	1973	1230	7060	1440	4070
Propylene glycol	24000	8000	9718	20000	6800	6660
Glycerin	4090	6199	8982	126000	5566	8728
PEG 400	28915	8550	9953	—	7312	9708
Dimethylacetamide	4620	3020	2800	5000	2640	2750
Dimethylsulfoxide	16500	5750	2500	17500	5360	8200

(From Ref. 48.)

of the solubility curve (B) may also minimize or reduce precipitation upon dilution. In this case, even concentration III will not precipitate upon dilution. Thus, a careful selection of cosolvent and drug concentration can prevent such occurrences upon IV injection or dilution with aqueous fluids.

BIOLOGIC EFFECTS OF COSOLVENTS

When selecting a cosolvent as a vehicle for a drug formulation, the compatibility of the solvent or solvent mixture with the appropriate tissues must be considered, as well as the potential for systemic effects. Occasional reports of systemic effects on the central nervous system (CNS, 28) or renal system (29) have been reported in humans after relatively large doses of cosolvents have been administered as part of a drug vehicle. In general, systemic effects of cosolvents are of particular interest

when they are used in drug formulations that are administered to animals during pharmacologic or safety evaluation of a drug. Budden (30) demonstrated CNS and muscle relaxant activity in mice for a number of commonly used cosolvents. It must be remembered that undesirable biological effects of a cosolvent depend on several factors that include the dose of cosolvent, route of administration, rate of administration, and concentration in the formulation. For example, a rapid bolus injection of a formulation containing a cosolvent could result in undesirable effects, which could be minimized or eliminated if administration is performed slowly or diluted with an isotonic vehicle prior to administration. When undesirable systemic or local effects of a particular cosolvent limit its use in a formulation, solvent blending that uses alternative solvents is in order.

Table 2 lists LD 50 data for various cosolvents in mice and rats and Table 3 lists the irritation data for various cosolvents when applied topically to the skin or eye. In addition, many product development scientists rely on the

Table 3 Irritation data for selected cosolvents^a

Cosolvent	Skin	Species	Eye	Species
Ethanol	400 mg (unoccluded)	Rabbit	79 mg	Rabbit
Propylene glycol	10% (2 days)	Man	100 mg (mild)	Rabbit
	500 mg (7 days, mild)	Hamster	500 mg (moderate)	Rabbit
Glycerin	500 mg (moderate)	Rabbit	126 (mild)	Rabbit
Dimethylacetamide	10 mg (mild)	Rabbit		
Dimethylsulfoxide	10 mg (unoccluded, mild)	Rabbit	100 mg	Rabbit
	500 mg (moderate)			
Isopropyl alcohol	500 mg (mild)	Rabbit	16 mg; 10 mg (moderate)	Rabbit

^aData expressed as minimum irritant dose using a 24-h (unless otherwise stated) Draize Test. Severity of reaction is listed when available. All tests performed on occluded skin unless stated otherwise.

(From Ref. 48.)

Table 4 List of parenteral products containing cosolvents

Trade name	Generic name	Manufacturer	Cosolvent composition	Route(s) of administration
BICNU	carmustine	Bristol Myers	100% dehydrated alcohol	IV infusion
Librium	chlordiazepoxide	Roche	20% propylene glycol	IM

(From Ref. 49.)

composition of past or currently marketed drug formulations as a safety guideline for new drug formulations. Tables 4–6 list the composition of various products that contain cosolvents, including products that are given parenterally, topically, and into the eye or ear.

Considerable interest exists in the local effects that cosolvents exert during IV and intramuscular (IM) injection. Several investigations have studied the hemolytic potential of cosolvents (31–35). Cosolvent-induced hemolysis of red blood cells has been studied under both static and dynamic flow conditions. Table 7 was abstracted from Krzyzaniak et al. (35) and compares the results of in vitro static and dynamic hemolysis experiments with the incidence of hemolysis observed in vivo for various vehicles containing cosolvents. In a separate publication that described the use of a dynamic method of hemolysis detection, both glycerin and propylene glycol were observed to produce significant hemolysis, while ethanol and PEG 400 did not (34). All four cosolvents were tested at a concentration of 50% in water. Propylene glycol was later reported to be nonhemolytic at a concentration less than 20% (35).

Phlebitis has been observed for several poorly soluble drugs that are formulated in cosolvent–water mixtures. Ward et al. tested several formulations of both water-soluble and water-insoluble drugs, as well as various cosolvent–water mixtures after injection in the rabbit ear (36). The cosolvent–water vehicles alone were not found to induce phlebitis. These studies indicate that the irritation was most likely caused by water–immiscible drugs.

A consideration of the local effects of cosolvents on muscle should be considered following IM injection. Brazeau and Fung (37) studied the effects of various cosolvents on muscle damage. The results are illustrated in Fig. 5. In general, glycerin (not shown) and propylene glycol produced more evidence of muscle damage, while PEG 400 was found to produce the least irritation. These results tend to parallel the hemolytic potential of cosolvents. Oshida et al. (38) suggested the use of hemolysis measurements as a way to predict muscle damage of various formulations. Brazeau and Fung also reported that the combination of PEG 400 with other, more irritating cosolvents was found to reduce the muscle damage induced by the more irritating cosolvent.

Other cosolvents, including glycerol formal, solketal, dimethylformamide, and dimethylsulfoxide, have been suggested as potential cosolvents for drug formulations; however, their safety has not been established. For additional information on these as well as other cosolvents, the reader is directed to the review by Spiegel and Noseworthy (39).

EFFECTS OF COSOLVENTS ON THE CHEMICAL STABILITY OF DRUGS

The influence of solvent polarity on the chemical stability of drugs depends on the nature of the reactants, products, and transition state of the reactants. This was discussed by Connors et al. (1) for various combinations of reactants. In general, if a vehicle is less repulsive to the transition state than another, an increase in the reaction rate will occur. Various situations arise, depending on the relative charges on the reactants. For example, when both reactants are ions (40):

$$\log k_{\varepsilon 2} = \log k_{\varepsilon 1} - \frac{Z_1 Z_2 e^2}{2.303 k T r} \left(\frac{1}{\varepsilon_2} - \frac{1}{\varepsilon_1} \right) \quad (11)$$

where $k_{\varepsilon 1}$ and $k_{\varepsilon 2}$ are the reaction rate constants in two different solvent media of dielectric constant, ε_1 and ε_2 , respectively, Z is the ionic charge, k is the Boltzmann constant, e is the electronic charge, T is the absolute temperature, and r is the distance between the two ions. For the reaction between an ion and a dipolar molecule (41):

$$\log k_{\varepsilon 2} = \log k_{\varepsilon 1} - \frac{Z \mu e \cos \theta}{2.303 k T r^2} \left(\frac{1}{\varepsilon_2} - \frac{1}{\varepsilon_1} \right) \quad (12)$$

where μ is the dipole moment and θ is the angle between the resultant dipole and the axis of collision of the two species. For two dipolar reactants (assuming alignment of the dipoles):

$$\log k_{\varepsilon 2} = \log k_{\varepsilon 1} - \frac{2\mu_1 \mu_2}{2.303 k T r^3} \left(\frac{1}{\varepsilon_2} - \frac{1}{\varepsilon_1} \right) \quad (13)$$

Eqs. 11, 12, 13 illustrate the concept that acceleration or deceleration of a reaction rate upon a change in solvent polarity depends on the charge of the reactants. For example, if ε_1 is water and ε_2 is an ethanol–water mixture, two oppositely charged ions will demonstrate a reduced stability in the ethanol–water system, whereas two similarly charged reactants will demonstrate an enhanced stability. This can be understood by realizing that water provides greater insulation to ions and polar species as compared to a cosolvent–water mixture. Thus, addition of cosolvents to water increases the attraction between oppositely charged species and increases the repulsion between similarly charged species.

While Eqs. 11–13 are useful in understanding the general medium effects on reaction rates, their ability to quantitatively predict reaction rates will most likely suffer from inaccuracies similar to those experienced with solubility prediction in mixed solvents. Dielectric constant

Table 5 Examples of ophthalmic and otic products containing cosolvents

Product name (manufacturer)	Active component(s)	Cosolvent composition
Chloroptic (Allergan)	Chloramphenicol	PEG 300
Americaine Otic (Medeva)	Benzocaine	PEG
Debrox Drops (Marion)	Carbamide peroxide	Glycerin, propylene glycol
Auralgan Otic (Wyeth-Ayerst)	Antipyrine, benzocaine, glycerin	Glycerin
VoSol Otic (Wallace)	Acetic acid	propylene glycol

(From Ref. 50.)

as a single parameter is not capable of quantitating all interactions among solvent and solute molecules. LePree and Connors (42) reported on the use of a phenomenological approach to predict reaction rates in mixed solvents. The approach is similar to the solubility studies reported by Khossravi and Connors (18) and uses complex equilibria to characterize solvent–solute interactions.

When water is a reactant in the degradation process, that is, when the reaction is hydrolytic, replacement of all or part of the water with a cosolvent may enhance the stability of the drug. This does not imply that solvolysis will not occur with solvents other than water. Indeed, many pharmaceutical solvents or solvent blends are sufficiently nucleophilic to participate in substitution reactions; however, they are often less reactive than pure water (43).

When cosolvents are used to enhance solubility, the potential effects on drug stability must be remembered. The benefit of the enhanced solubility must be weighed against potentially undesirable effects on drug stability.

Cosolvents may also contain impurities that can initiate or catalyze oxidative degradation. PEGs are well-known initiators due to their ability to form unstable peroxides (44). Likewise, the heavy metal content of a cosolvent can vary from vendor to vendor or lot to lot. The use of such cosolvents in formulations of drugs susceptible to oxidation requires that strict limits be placed on specifications for the heavy metal or peroxide content of the cosolvent.

EXAMPLES OF THE USE OF COSOLVENTS FOR THE FORMULATION OF LIQUID DOSAGE FORMS

Oral Dosage Forms

Ethanol has been used traditionally as a cosolvent for oral solutions. It has been incorporated with sucrose in elixir

Table 6 Examples of topical products containing cosolvents

Product name (manufacturer)	Active component(s)	Cosolvent composition
Dermal Preparations		
Benadryl Itch-Stopping Spray (Warner-Lambert)	diphenhydramine HCl	alcohol, glycerin
Erythromycin topical (various)	Erythromycin	55–77% ethanol propylene glycol
Lotrimin solution (Schering)	Clotrimazole	PEG 400
Diprolene lotion (Schering)	Betamethasone dipropionate	30% isopropanol propylene glycol
Lamisil (Novartis)	terbinafine HCl	28.7% ethanol propylene glycol
Effudex (ICN)	5-fluorouracil	propylene glycol
Lidex (Medicis)	Fluocinonide	35% alcohol propylene glycol
Lotrimin AF Solution (Schering-Plough)	miconazole	PEG
Rogaine (Pharmacia-Upjohn)	minoxidil	60% alcohol propylene glycol
Mouth and Throat Preparations		
Anbesol (Whitehall-Robbins)	Benzocaine, phenol	PEG propylene glycol
Glyoxide (SKB)	Carbamide peroxide	glycerin propylene glycol
Listerine (Warner-Lambert)		21.6% alcohol

(From Ref. 50.)

(From Ref. 35.)

formulations, the alcoholic content of which may vary from 3–78%. These formulations resulted in solubilization and/or stabilization of various drugs and have more favorable taste as compared to that of other solvents. Its use is often undesirable, however, in oral preparations intended for pediatric patients or other patients who cannot tolerate the effects of ethanol. Ethanol may also accentuate the saline taste of ionic solutes (45). Propylene glycol has been suggested as an appropriate substitute for ethanol in oral solutions; however, its use in pediatric formulations should be carefully examined in light of previous reports of toxicity (46). In addition, the objectionable taste of propylene glycol may require the addition of flavoring

agents. Liquid PEGs have been used as vehicles for soft gelatin capsules as well as pediatric elixir formulations.

Parenteral Dosage Forms

The use of cosolvents in small-volume parenteral preparations is often critical due to the limited volume of solution that can be administered by a single injection. Thus, the required dose of drug must often be incorporated in 1 or 2 mL of solution. Table 6 lists parenteral products containing cosolvents. The cosolvents most often used include ethanol, propylene glycol, glycerin, PEG 400, and, sometimes, dimethylacetamide. Other cosolvents, such as DMSO, have been used as solvents for parenteral formulations of experimental anticancer agents; however, their use is restricted due to toxicity and potential incompatibilities with plastic administration devices (47).

Irritation, and hemolysis are primary considerations when choosing a cosolvent for parenteral preparations. Concentration and route of administration are important factors that determine the incidence and severity of local reactions.

Ophthalmic and Otic Dosage Forms

Ophthalmic formulations sometimes contain cosolvents, such as propylene glycol or PEG 300, as part of the vehicle. The greatest limitation to the use of cosolvents in ophthalmic preparations is their irritation potential. For example, ethanol is too irritating to be used in the eye (Table 3). Osmotic effects of cosolvents are also important, and the strong osmotic effect of glycerin combined with its poor solubilizing power limit its usefulness in ophthalmic preparations.

Fig. 5 Myotoxicity of various cosolvents as a function of % cosolvent in water. ○ = propylene glycol, Δ = ethanol, □ = Polyethylene glycol 400. (From Ref. 37.)

Propylene glycol, PEG, glycerin, and isopropyl alcohol have been used in otic formulations. Table 5 contains a list of ophthalmic and otic preparations containing cosolvents.

Topical Dosage Forms

Liquid preparations intended for dermal application contain the largest variety of cosolvents. They most commonly include ethanol, isopropanol, propylene glycol, glycerin, and PEG 400. Irritation and sensitization are important considerations in choosing a cosolvent for dermal use. In addition, it may be necessary to test new compounds for photoirritation or photosensitization reactions.

Other cosolvents, such as DMSO, demonstrate skin penetration enhancement properties for a number of compounds. Although this could be a highly desirable property for many drugs, the use of DMSO as a solvent for dermal application has not been approved.

Preparations that are applied topically to the mouth and throat have contained glycerin, ethanol, propylene glycol, and PEG. Both systemic and local toxic effects would need to be considered in choosing a solvent system for these preparations. Table 6 contains a list of dermal and topical mouth and throat products that contain cosolvents.

COSMETICS AND THEIR RELATION TO DRUGS

Martin M. Rieger

M&A Rieger, Morris Plains, New Jersey, U.S.A.

INTRODUCTION

Under the Food, Drug, and Cosmetics Act (FDCA, 21 U.S. Code 301), the Food and Drug Administration (FDA) of the United States has the authority to regulate foods, prescription (Rx) drugs, over-the-counter (OTC) drugs, and cosmetics. The FDA also administers a second statute, the Fair Packaging and Labeling Act (FPLA, 15 U.S. Code 1400). In order to administer this complex task, the FDA depends on the legalistic and statutory definitions of drug and cosmetics in the FDCA. Nevertheless, the public's interpretation of what constitutes a drug or a cosmetic may differ somewhat from that of regulatory agencies. Philosophically and historically, a cosmetic is a product that helps improve external appearance and has the ability to hide, or at least distract from, unwanted stigmata or skin defects.

A product that changes the color of hair is a cosmetic, as is a product intended to increase the skin's tendency to tan by exposure to sun. This traditional view remains ingrained in the consumer's mind but may not be judicially valid. A change in hair color, for example, can be effected by the following: 1) a wig, which might be viewed as an article of clothing; 2) a variety of dyeing processes, which are properly identified as cosmetic changes; and 3) possibly by a variety of ingested or topically applied substances that gradually alter the hair follicle's ability to synthesize melanin, which should be classified as a drug effect. The common goal of these three approaches is to effect a change in appearance, the key objective of all cosmetics. The method by which this goal is achieved differentiates the three hair "coloring" processes and makes a product a drug or a cosmetic. This can create some confusion, as is demonstrated by a consideration of sunscreen products. Sunburn prevention by topical products was for years considered within the scope of cosmetics, even though ultraviolet-B (UV-B) light absorbers were incorporated into these "cosmetics." The cosmetic industry responded rather calmly when the FDA's review of OTC drugs included suntan preparations and sunburn preventives. What for years had been a cosmetic suddenly became a drug by legislative or administrative fiat. The FDA's rationale is justifiably

based on the concept that sunburn prevention is prevention of disease. Adding an ingredient that enhances the ability of melanocytes to produce melanin in the skin would be viewed as a cosmetic by the user. The FDA is likely to accept cosmetic (color change, appearance) claims for such a product, but a definition of a drug would become mandatory if the melanin is claimed to protect against sunburn. The implication that a parasol intended to prevent exposure to sun is a medical device has not been judicially examined.

One must recognize that the differentiation between cosmetics and drugs is complex and is blurred by the interplay of consumer perception, commercial interest, and statutory interpretation by regulatory agencies, with the ultimate decision in the hands of the judiciary. For these reasons, differences between drugs and cosmetics are discussed in the next section on the basis of existing U.S. laws, the product's composition, and safety and efficacy. Laws and rules covering the distinction between cosmetics and drugs differ from country to country. For this reason, marked divergence from U.S. practices will be noted in this survey.

COMPARISON ON THE BASIS OF U.S. LAW

Definitions

The sharpest distinction between a drug and a cosmetic is based on the statutory definitions in the Federal Food Drug and Cosmetic Act (21 USC 301 et seq.). Cosmetics are clearly defined as:

- 1) articles intended to be rubbed, poured, sprinkled, or sprayed on, introduced into, or otherwise applied to the human body or any part thereof for cleansing, beautifying, promoting attractiveness, or altering the appearance, and 2) articles intended for use as a component of any such articles; except that such term shall not include soap.

On the other hand, drugs are defined as follows:

The term drug means: (A) articles recognized in the official United States Pharmacopoeia, official

Homeopathic Pharmacopoeia of the United States or official National Formulary or any supplement to any of them; and (B) articles intended for the use in the diagnosis, cure, mitigation, treatment, or prevention of disease in man or other animal; and (C) articles (other than food) intended to affect the structure or any function of the body of man or other animals; and (D) articles intended for use as a component of any articles specified in clause (A), (B), or (C); but does not include devices or their components, parts, or accessories.

These definitions may differ from the interpretation of the consumer or from generally accepted usage, but courts will adjudicate exclusively on the basis of these statutory definitions. It is clearly the intent of the product, not necessarily its performance, that is used judicially to classify a product as a drug or as a cosmetic. A skin-care product intended to beautify by the removal of wrinkles is both a cosmetic (alters the appearance) and a drug (affects a body structure). Historically and intuitively, the requirements for a drug are more stringent than those for a cosmetic, and the regulatory agency and the courts tend to apply the more stringent requirement to a product that may be perceived to be both a drug and a cosmetic. Table 1 includes a listing of products classified by the FDA as cosmetics. Some of the products are considered drugs or quasi-drugs in other countries.

The Food and Drug Administration's Tasks

The FDA is authorized to enforce the FDCA and the FPLA. The FDA's tools include inspection and seizure, which may be applied equally to drugs or cosmetics.

The FDCA prohibits the use (or presence) of poisonous or deleterious substances. Their presence makes a cosmetic "adulterated" or "misbranded." In this regard, no significant distinction is made between drugs and cosmetics. Similarly, good manufacturing practices (GMPs) are applicable to drugs and with minor changes to cosmetics. Products that are manufactured under conditions that are in violation of the GMPs may become subject to seizure. In recent years, the FDA has not initiated formal cases against violators of cosmetic regulations; instead, the FDA has relied on so-called Warning Letters to obtain compliance without recourse to complicated legal action.

In contrast to Rx drugs, OTC drugs and cosmetics are not subject to preclearance. Preclearance is specifically designed to prevent the introduction of dangerous or undesirable drug entities into the market. The restrictions on ingredients are most severe in the case of OTC drugs and preclude introduction of untested drugs or combinations. In fact, a "new chemical entity," which might be entirely suitable for introduction as an OTC drug, requires workup via the new drug application (NDA) process. The approval of Rx and OTC drugs by the FDA is, in principle, based on the performance of the drug entity. Efficacy against the disease, bioavailability, and lack of adverse side effects are of primary importance. Thus, judicious choice of drug excipients is required for all drug approvals. Nevertheless, in the absence of an FDA-approved list of cosmetic ingredients, the cosmetic manufacturer has the responsibility to provide products that are not injurious to the user under the expected conditions of use. Some ingredients are specifically restricted, and a regulation requiring safety substantiation exists. These will be discussed in the section entitled "Restrictions on the Use of Ingredients."

Table 1 List of products (recognized as cosmetics in the United States)

Baby preparations	Creams, lotions, oil, powders, shampoos
Bath preparations	Bubble baths, capsules, oils, salts, soaps and detergents, tablets
Cleansing preparations	Creams, douches, liquids and pads, lotions, personal cleansing products
Dentifrices	Aerosols, breath fresheners, liquids, mouthwashes, pastes, powders
Fragrance products	Colognes and toilet waters, deodorants, fragrances, perfumes
Hair products	Depilatories, dressings, dyes and colors, grooming aids, lighteners, miscellaneous rinses, permanent wave products, shampoos, sprays, straighteners, tints, tonics, wave sets
Makeup preparations	Blushers, eyebrow pencils, eyeliners, eye makeup preparations, eye makeup removers, eye shadows, face powders, facial makeups, fixatives, foundation makeups, leg and body paints, lip glosses, lipsticks, mascaras, rouges
Miscellaneous products	Paste masks, powders (men's, women's, talcums)
Shaving preparations	Aftershaves, beard softeners, shaving creams (aerosol, brushless lather), preshaves
Skin care preparations	Body and hand preparations (moisturizers), eye creams, face and neck preparations, fresheners and astringents, suntan gels

Color Additives

Color additives are of particular importance to the formulation of cosmetics. Dyes and pigments not only make products more attractive but also are vital to any product that is intended to alter the color of any part of the body. Color additives are regulated meticulously by the FDA, and only some general information on the current regulatory status of colorants in the United States can be provided.

Certified color additives are synthetic organic dyes that are described in an approved color additive petition. Each manufactured lot of a certified dye must be analyzed and certified by the FDA prior to usage.

Color lakes are pigments that generally consist of an insoluble metallic salt of a certified color additive deposited on an inert substrate. These lakes are subject to the color additive regulations of the FDA and must be certified by the agency prior to use.

Color additives that are not classified as certified color or color lakes are identified as *noncertified color additives*. Each of these substances is the subject of an approved color additive petition, but individual batches do not require certification by FDA prior to use.

The fourth major class of color additives is *hair colorants*. These compounds or their mixtures may be used only to color scalp hair and may not be used in the eye area. Use of these colorants is “exempt,” that is, the so-called coal-tar hair dyes may be sold with cautionary labeling, directions for preliminary (patch) testing, and restrictions against use in or near the eye.

Soap Exclusion

Soap is specifically excluded from cosmetics in the FDCA, and no cosmetic or drug regulations are applicable to soap. The FDCA fails to define the term *soap*, but the FDA has ruled that a product is a soap if the bulk of the nonvolatile matter is the alkali salt of a fatty acid and if its deterative properties are due exclusively to the fatty acid salt. In addition, the product must be labeled as a soap. A product is identified as a shampoo when it consists, e.g., only of aqueous potassium oleate. It then must conform to cosmetic regulations.

The term *soap* thus has two meanings. The first is the FDA’s definition, which is used for legal purposes. The second is the generic sense, whereby soaps may refer to cleansing products that may not meet the specifics of FDA’s definition. Such products must, therefore, be labeled as cosmetics. The Federal Trade Commission (FTC) and the Consumer Products Safety Commission (CPSC) handle the regulatory control for soaps.

COMPARISON ON THE BASIS OF COMPOSITION

Drug Ingredients Versus Cosmetic Ingredients

On the basis of the Drug Efficacy Study Implementation (DESI) review, which began in 1962, the FDA ultimately concluded that of about 16,000 claims made for 3400 Rx drugs, only about 2300 drugs were effective for at least one indication. Today, Rx drugs must undergo the NDA process, which, for all practical purposes, is a critical preclearance procedure. As the work on the DESI review neared completion, the FDA initiated the so-called OTC review in 1972. The FDA classified some 250,000 drugs into about 55 therapeutic groups. The panels that reviewed each group had the responsibility to establish the safety and efficacy of each OTC drug and to restrict claims for these drugs to those the panel considered appropriate for a given drug or combination of drugs. It is apparent that the marketability of a drug—Rx or OTC—requires the presence and bioavailability of an identifiable drug entity that can be expected to exert some therapeutic benefit. No such legal requirement for the use of raw materials exists in cosmetics. As a rule, the presence of and claim for any component in a cosmetic that may have a therapeutic effect converts such a cosmetic into a drug.

The FDA has classified the following topically applied products as OTC drugs on the basis of safety and efficacy review of the drug(s) constituents:

- Acne products
- Antidandruff products
- Antimicrobial products
- Antiperspirant products
- Astringent products
- Oral care products
- Skin-protectant products
- Sunscreen products
- External analgesic products

In other countries, some of these products are considered cosmetics.

Some of the actives used in the past in such products have been classified as Category I, i.e., safe and effective. Usage of these agents and the claims made for the finished product make these products OTC drugs, not cosmetics.

The activities of the OTC panels are not yet completed, although most of the tentative final reports have been published. However, no definitive rulings have been made or subjected to judicial review. It appears at this time that the ingredients reviewed by the OTC panels can be used in cosmetics as excipients and the like. To repeat, their use, together with drug or therapeutic claims, transforms the cosmetic into a drug, in which case the labeling and claim

structure must conform to those established for OTC drugs. The designation "cosmetic" places almost no restriction on the use of components. However, claims for therapeutic efficacy convert any cosmetic into a drug, as interpreted by the FDA. The regulations do not restrict the use of a drug substance for purposes unrelated to its drug status.

COSMETICS AND THEIR RELATION TO DRUGS

Restrictions on the Use of Ingredients in Cosmetics

The review of active drugs by the OTC panels was limited to relatively few drug entities, but the cosmetic industry employs thousands of ingredients, including many of plant and animal origin. Many typical cosmetic ingredients are identical to the components used in Rx and OTC drugs, but only very few cosmetic ingredients are subject to restrictions by the FDA. These include mercury compounds, except those used as preservatives in products intended for use in or near the eye. Others are bithionol, vinyl chloride, halogenated salicylanilides, zirconium compounds in aerosol products, chloroform, chlorofluor-carbon propellants, and hexachlorophene. With regard to cosmetic ingredients, the FDA has placed the responsibility for substantiating their safety squarely on the producer. Such safety substantiation also includes finished products. Each ingredient used in a cosmetic product and each finished cosmetic product shall be adequately substantiated for safety prior to marketing. Any such ingredient or product whose safety is not adequately substantiated prior to marketing is misbranded unless it contains the following conspicuous statement on the principal display panel: Warning—The safety of this product has not been substantiated [21 CFR, Par. 740].

These regulatory activities and the need to demonstrate to the public that the cosmetic industry as a whole is prepared to accept responsibility prompted the Cosmetics, Toiletries and Fragrance Association (CTFA) in 1976 to establish the Cosmetic Ingredient Review (CIR) for the purpose of evaluation and review of the safety of the ingredients used in cosmetics. The CIR process established a system for prioritizing ingredients based on frequency of use, concentration used, area of use, frequency of application, use by sensitive subgroups, likelihood of biologic activity, and consumer complaints. This is a scientific review of worldwide data, and nonvoting members from industry and consumer groups participate in the deliberations. In order to speed up the review process and to avoid duplication, the CIR expert panel may defer study of substances that are already under review by other

safety programs. The most important of these are those by the Research Institute for Fragrance Materials (RIFM) and the Flavor and Extract Manufacturers Association (FEMA). The former establishes the safety of fragrance components; its funding and concept permit expenditures for safety testing of substances. The latter addresses issues related to the safety of individual flavor materials. The reviews by the CIR panel are available from the CTFA (1101 17th St., N. W., Washington, D.C., 20036-4702) and have appeared over a period of years in the *Journal of the American College of Toxicology*.

Although the CIR process is sponsored by the CTFA, the latter will conduct safety studies for substances considered crucial to the survival of the cosmetic industry. The CTFA will also establish and pay for research required to confirm the stability, chemical purity, and safety of various cosmetic ingredients. These activities are part of the cosmetic industry's technically oriented self-regulation program. Similar programs exist in the pharmaceutical industry.

RIFM has recommended discontinuance of the use of acetyethyl tetramethyltetralin, 6-methylcoumarin, musk ambrette, and musk ketone. Another self-imposed ingredient restriction concerns the use of potential nitrosating agents in products containing various (secondary) alkanol amines, in light of the hazard of nitrosamine formation. In the European Union, (E.U.), the use of *tri*- and *di*-ethanolamine is restricted.

One of the key self-regulatory procedures in the cosmetic industry is the voluntary reporting process of adverse reactions. The program is intended to provide data on the type and frequency of adverse reactions reported by consumers or by their medical advisors to the industry. It is an important means of detecting problems that are not treated in hospital emergency rooms (i.e., documented in the National Electronic Injury Surveillance System, NEISS) or do not reach poison control centers.

Practical Aspects

For practicing formulators, the border between cosmetics and drugs is not clear. Drug entities for which claims are made on the label differentiate drugs from cosmetics. However, the same or chemically similar excipients and formulation aids are widely used in cosmetics and drugs. Finally, one must recognize that cosmetics may include groups of substances not normally found in drugs. These similarities and differences are illustrated in Table 2. Substances considered drugs by U.S. law have been excluded from the table. This listing is not comprehensive and is presented for illustrative purposes only.

Table 2 Common usage of selected ingredients in cosmetics and drugs and cosmetics

Function	Cosmetics (primarily)	Cosmetics and Drugs
Abrasive	Oatmeal	Dicalcium phosphate
Absorbent		Kaolin, silica
Antifoam		Simethicone
Antioxidant		Ascorbic acid, BHA, BHT, tocopherol
Antistatic	N-Lauroyl- β -Alanine, stearyl/dimethylbenzylammonium chloride [INCI nomenclature: CAS 68650-39-5]	
Binder		Hydrophilic gums, Polyvinyl acetate, starch
Bulking agent		Cellulose, silica
Chelator		Citrates, EDTA and salts, glucuronic acid
Cleanser	Triethanolamine laurylethersulfate, lauryl betaine	Sodium Laurylsulfate, poloxamer 188
Coemulsifier	Beeswax	Fatty alcohols
Emollient	Apricot kernel oil	Cocoa butter, dibutyl sebacate, dioctyl adipate, isopropyl myristate, lanolin, mineral oil, squalene
Emulsifier	Sodium lauroyllactylate [INCI nomenclature: CAS 13557-75-0]	Alkoxylated fatty acids, alkoxylated fatty alcohols, fatty acid salt, lecithin, monoglycerides, poloxamers, polysorbates, sorbitan esters
Folkloric additive	Plant and animal extracts, protein derivatives	
Humectant	N-Acetyl monoethanol-amide, pyrrolidone carboxylic-acid	Glycerin, sorbitol, urea, sodium lactate
Lubricant (hair and skin)	Mink oil, sodium hyaluronate	Coconut oil, lanolin, olive oil, petrolatum
Plasticizer	Ethyltoluenesulfonamide	
Preservative	1,3-Dimethylol-5, 5-dimethyl hydantoin, Quaternium-15 [INCI nomenclature: CAS 4080-31-3]	Camphor, dioctyl sebacate Imidazolidinyl urea, parabens phenoxyethanol
Solvent and viscosity reducer		Acetone, ethanol, ethyl acetate, glycerin, hexylene glycol, <i>i</i> -Propanol, propylene glycol, toluene
Suspending agent	Sodium methylnaphthalene sulfonate [INCI nomenclature: CAS 26264-58-4]	Carbomer, cellulose derivatives, clays
Thickener		Behenyl alcohol, polyethylene, polyisobutene, polyoxyethylene 14,000, tristearin
UV light absorber	Butyl methoxybenzoylmethane	Drometrizole

The overlap on the basis of ingredient usage is apparent from an examination of column 3.

Labeling of Cosmetics

An important ingredient-related topic is cosmetic ingredient labeling. Advocates of consumers' rights have suggested that the public would benefit from full disclosure of the composition of cosmetic products. Pursuant to the regulations by the FDA and the FPLA, all cosmetics are now required to carry the following information on labels: 1) a statement of the identity of the product; 2) a statement of the net quantity of contents; 3) a statement of the name and place of business of the manufacturer, packer, or distributor; 4) a list of the ingredients included in the product in order of predominance; and 5) cautionary or warning language [21 USC 321 (k); 15 USC 1459 (b); 21 CFR 701.10].

Except the aforementioned labeling for item 4, similar requirements exist for Rx and OTC products at the time of this writing. Labeling of all constituents in OTC drug products is still under consideration. The listing of ingredients in cosmetics must be in descending order of predominance, with some exceptions for components present as minor constituent and color additives. In order to achieve uniformity for identification, the CTFA has continuously created shorthand nomenclature for all cosmetic ingredients. The "naming" process is similar to that employed by USAN (U.S. Adopted Name). Many names and chemical descriptions of cosmetic ingredients have been reviewed and accepted by the FDA (for the purpose of using these names on labels). As a result, cosmetics in the U.S. are now labeled in accordance with the nomenclature and the rules of the International Nomenclature of Cosmetic Ingredient Dictionary (INCI Dictionary; 1). This approach has been accepted in the E.U., where the same names (with minor modifications) are used. "Harmonization" of names is a continuing process to make these names linguistically acceptable throughout the world.

COMPARISON ON THE BASIS OF SAFETY AND PERFORMANCE

Safety

Users know that, as a rule, Rx drugs are more likely to cause adverse side effects than OTC drugs. This is an obvious result of the nature and of the distribution system for these products. Prescription drugs are administered under the supervision of a physician, who has the

responsibility and moral obligation to monitor the patient's progress. However, OTC drugs may be used ad lib by the uninformed, who may not always be competent to diagnose the underlying disease or to recognize adverse side effects. In this respect, cosmetics resemble OTC drugs except that cosmetics are used repeatedly and over extended periods of time. Thus, the requirements for the safety of cosmetics should be, in fact, much more stringent than those for many drugs. The level of side effects or adverse effects that can be tolerated by manufacturers of cosmetics is virtually nil. Of particular concern is the sensitizing potential of components during prolonged and repeated use. Photosensitization is another phenomenon that has led to the removal of some cosmetic ingredients from the list of routinely employed substances.

Elegance

Elegance is not a primary concern in the case of Rx drugs but impacts marketing of OTC drugs and helps to ensure patient compliance. By contrast, any feature that detracts from the elegance (appearance, odor, texture, etc.) of a cosmetic interferes with its marketability and acceptance. As a matter of fact, cosmetic elegance is the essential attribute of a successful cosmetic product.

Performance

Performance is the one issue in which cosmetics and drugs are different. Drug efficacy is assessed on the basis of cure or prevention of disease. The FDA has established that cosmetic products that exert therapeutic effects are drugs. As a result, some traditional cosmetics were converted into drugs via the OTC panel process. Any performance claims for these OTC products are limited to the wording approved during the OTC review process.

Claims for (nondrug) cosmetics may be, for example, fashion-oriented (color), beauty-oriented (hiding of blemishes), or texture-oriented (emollient or lubricant). These, and related claims, are easily perceived and can be readily documented. More complex issues arise when cosmetic claims are made for age-related or reparative skin-care preparations. In the past, various regulatory agencies have been permissive with regard to cosmetic puffery claims. More recently, claims made for some cosmetics suggest to consumers that the product may exhibit a druglike effect, as defined by statute. A Commissioner of Food and Drugs has labeled these claims "daring" (2). Advertising copy that implies that a product nourishes the skin, is active, causes tingling, tightens the skin, discourages wrinkle formation, is prepared by a pharmaceutical company, or performs like

a face-lift may be false and misleading if the product does not perform. On the other hand, the product is considered a drug if it performs as claimed. Aside from drug results, claims for skin or hair benefits require documentation for commercial purposes (advertising and promotion). Thus, claims for performance are likely to run afoul of FTC rules. In the E.U., however, claims for efficacy require substantiation by regulation. Guidelines for documenting cosmetic performance exist in Europe but not in the United States (3). On the other hand, the FDA has a powerful tool for stopping unsubstantiated claims. A claim for wrinkle "removal," even on a temporary basis, may make a cosmetic product into a drug. Thus, the cosmetic industry is as tightly controlled as the Rx industry. Whenever a new indication for an existing drug constituent is claimed or whenever a druglike claim is made for *any* ingredient, a new drug application is required.

Shelf Life

Cosmetic preparations need not be labeled for outdating. This does not imply that cosmetic products must (or do) exhibit indefinite stability. The physical and chemical stability of cosmetics is routinely studied by the same procedures as those used for Rx or OTC drugs. Since cosmetic products do not contain active drug entities, the chemical stability of *any* component may be critical to the performance of the product: The components of a fragrance product require monitoring; the performance of a hair-waving preparation may depend on alkalinity and the chemical integrity of the reducing agent.

Physical stability affects cosmetic elegance, for example, by the breaking of an emulsion. Moreover, physical stability may also affect efficacy, as is the case during settling of a pigment in a nail lacquer that might then no longer be readily redispersible. A similar type of instability may occur as a result of the settling of an antiperspirant compound in a suspension aerosol. In these cases, neither the cosmetic (nail lacquer) or the OTC drug (antiperspirant) performs as claimed and may be considered misbranded or mislabeled.

As a rule, therefore, the demands of chemical and physical stability are similar for drugs and cosmetics. Under certain circumstances, the demands on physical stability may be especially critical as, for example, in hand and body lotions that have to perform under tropical conditions after having been exposed to the heat of the sun on the beach or after storage under arctic conditions in a ski hut.

The criteria for microbiologic cleanliness of cosmetic products are especially complex. Like a drug, a cosmetic is deemed adulterated if: 1) it bears or contains any poisonous or deleterious substance which may render it

injurious to users on the conditions of use as are customary or usual; 2) it contains in whole or in part of any filthy, putrid, or decomposed substance; and 3) if it has been prepared, packed, or held under unsanitary conditions where it may have become contaminated with filth, or whereby it may have been rendered injurious to health [Sect. 601, FDCA].

Cosmetic companies adhere to FDA-mandated GMPs or to GMPs promulgated by the CTFA with regard to housekeeping, cleaning, and sanitizing of equipment, and purity of raw materials and process water. Water is a particularly important component of finished cosmetics. Its purity is closely monitored to avoid the inadvertent introduction of contaminating biota into products. The GMPs established by the FDA are available in 21 CFR, Part 211, and the CTFA has published similar recommendations in the form of Quality Assurance Guidelines for Cosmetic Manufacture.

The final check on purity is on the finished product. The high water content and the inclusion of nutrients for unwanted microbiota make cosmetics subject to microbiological contamination. Thus, topical OTC products and cosmetics require preservation and a final check before distribution. Preservative systems and GMPs usually ensure delivery of essentially uncontaminated cosmetics. The microbiologic requirements recommended by the CTFA include the following: 1) baby products: less than 500 microorganisms/g; 2) eye products: less than 500 microorganisms/g; 3) oral products: less than 1000 microorganisms/g; (4) all other products: less than 1000 microorganisms/g; and 5) pathogens should be absent.

The use of preservatives to achieve the desired low levels of contaminating microorganisms is required. Some liquid cosmetic products do not support the growth of microorganisms (e.g., alcohol-based aftershave), while others are excellent growth substrates (e.g., a protein-containing hair conditioner). Because consumers frequently introduce microorganisms during normal product use, some cosmetic manufacturers may require that their products be self-sterilizing. This is a difficult task and not always achievable. A final check for levels of microorganisms is, nevertheless, desirable.

Relation to Health-Care Providers

Like the drug industry, the cosmetic industry requires animal toxicology and human testing to establish the safety of its products. As a rule, most cosmetic products are quite innocuous upon ingestion, even though they may cause laxation or act as emetics. The industry makes a deliberative effort not to market products that might elicit

toxic syndromes when ingested or applied topically. The former type of problem is usually handled by poison control centers and routinely (in 90% of all cases) involves ingestion by children. The number of fatalities was reported as nil between 1971 and 1978.

Dermatologists see many patients who have used cosmetic products properly but still report adverse reactions. The cosmetic industry is conscious of the need to provide products that do not elicit irritation or allergic responses during use. For this reason, the cosmetic industry depends on all types of patch and related testing by dermatologic laboratories to establish the safety of a given product in a predictive fashion. A whole battery of test protocols is available, and hundreds of subjects are tested routinely by dermatologists before product marketing (4).

Topical drugs and cosmetics have the potential of penetrating the skin. In the case of a topical drug (e.g., an antiinflammatory steroid), localized permeation may be a desirable feature. Penetration of cosmetics into and through the skin may elicit undesirable effects, especially since consumers may apply two or more products to the same site. Thus, in contrast to topically used Rx drugs, cosmetics should be retained on the skin with minimal penetration. Dermatologists also recommend cosmetics to patients as, for example, in cases of dry or chapped skin. Clearly, the cosmetic industry–physician–user relationship is not very different from that existing in the drug industry.

COSMETIC OR DRUG?

Formulators and marketers require an answer to the question of whether a given product is a cosmetic or a drug. Some of the answers are almost obvious. In the United States, a product is a drug if a drug claim is made for the preparation. The inclusion of a new chemical entity on which a therapeutic claim is based requires filing of a NDA; a product containing such a substance is automatically viewed as a drug. A typical example is a suntan product that adds an UV light-absorbing substance that was not reviewed by the OTC panel but was previously used as a sunscreen. Although the product in question was labeled as a drug, the FDA ruled that this clearly constituted use of an unapproved *new* drug substance. The addition of an OTC-reviewed sunscreen into a cosmetic makeup preparation—without claims for sun-protective action but with the indication that the product contains a sunscreen for the purpose of reducing UV light-induced skin aging—could be considered a drug use in the United States.

A soap to which an OTC Category I antimicrobial agent has been added is converted into a drug. This raises an interesting secondary issue. Soaps may be tinted with noncertified color additives. This inclusion of the antimicrobial requires not only drug labeling but also reformulation with approved colorants.

As a rule, the status of the product is determined by the claims made for it and its intended purpose. The use of aluminum chloride, a Category I OTC antiperspirant, as an astringent probably does not confer drug status on the product. It was already noted that certain OTC Category I skin protectants, such as petrolatum, can be used freely in cosmetics as long as no drug claims are made for the product. Numerous other issues might arise, and each one might require specific adjudication. An example is the use of an approved sunscreen in a cosmetic product to preserve it against UV light deterioration. Since the intent of the sunscreen's use is clearly not drug related, the product will probably be considered a cosmetic.

SUMMARY

Cosmetics and drugs are distinctly different on the basis of U.S. law. In principle, cosmetics may not contain ingredients that treat or prevent disease or alter the structure or function of the human body. The objective of cosmetics is limited to the enhancement of appearance.

The ingredients used in cosmetics to a large extent are the same as those employed in drugs, with the exception of components that are intended to cure, alleviate, or prevent disease.

The demands on product stability and manufacturing practices are essentially the same for cosmetics and drugs.

Finally, important differences are seen in judging the performance of cosmetics and of drugs. Consumers assess cosmetics based on the products' performance vis-à-vis the demand for better appearance. On the other hand, drugs are assessed on their ability to prevent or improve a disease state.

DNA PROBES FOR THE IDENTIFICATION OF MICROBES

Wayne P. Olson

Consultant, Beecher, Illinois, U.S.A.

INTRODUCTION AND SCOPE

In 1997 and the first quarter of 1998, when much of the first version of this article was written (1), what we hereafter refer to as DNA probes were used primarily by those performing genetic-related research. Today (mid-2000), oligonucleotide (DNA, RNA, and related) probes in several guises are a growth industry in biotechnology, and their applications are widespread. In 1995, Theta Reports (*Gene Therapy/DNA Probes/PCR Markets*) predicted a phenomenal growth in polymerase chain reaction (PCR), DNA probes, and the successful use of gene therapy—they were correct about the first two. In 1996, the Frost & Sullivan Market Intelligence indicated that the 1995 market for DNA probes had been over \$145 million, and predicted that it would reach \$1.4 billion by 2003 (*U.S. DNA Probe Markets*). Also in 1996, Business Communications Co., Inc., made similar predictions (*Advances and Opportunities in DNA Testing and Gene Probes*). DNA probes are the fastest growing area of in vitro diagnostics (2), expanding at the rate of 25% per year.

The most important differences between the earlier and the current version of DNA probes (1) relate to the following:

- Literature and applications have boomed; cumulative citations listed by Medline for “DNA probes” are currently 79,270.
- Applications—especially of PCR—now embrace most aspects of life sciences, including agriculture, food science, and nonmicrobial disease states, as well as areas relating to human diseases.
- Use of oligo-on-a-chip (DNA- or RNA-based array, also referred to in some instances as microchip) has burgeoned in pharmaceutical/biotech R&D. This approach, if not yet predominant, is becoming so in many applications.
- Antisense therapeutics, which had lost favor due to a well-publicized Phase-I human death in mid-2000, are already rebounding. Some forms of antisense show very high potential as antimicrobials.

To focus the current version of “DNA probes” on microbiological and related issues, together with

literature not explored in the previous version (1) some background material has been abbreviated. The reader unfamiliar with the fundamentals of DNA probes is urged to consult Vol. 19, Ref. 1 for introductory particulars. Table 1 of that article is repeated herein as Table 1, but without references. This author also recommends that the genomics tyro read one or more of the basic references (3–5), of which the article by Keller and Marak is the most germane. Additional basic texts not cited in (1) are listed in Table 1. Editors of those texts, who are significant contributors to the scientific literature, include (to my knowledge) Clapp, Higgins, Kricka, Marak, and Persing. Presumably, the others also do fundamental research but I have not read their papers.

Rapid growth areas of science, such as oligo probes, are referenced most rapidly on the Internet. Formal print publication may appear 1–3 years after completion of the work. Many, but not all, Internet publications are refereed in a manner similar to that for print publications. Therefore, many of the references herein are from the Internet.

Although I have cited a very small proportion of the patent, regulatory, and market literature herein, the reader should note that

1. Many productive scientists choose to file for letters patent in lieu of, rather than in addition to, conventional publication.
2. Negative findings may not find their way into scientific literature for a long time, if ever.
3. For a new commercial venture, first-rate technology is often insufficient; good business practice and adequate financing are equally important. Therefore, many small operations disappear.

Follow-up on vanished companies and products is difficult, unless they are acquired. For example, Biotech Research Laboratories and their peptide nucleic acid oligos (PNAs) were acquired by Boston Biomedica, Inc. Tracking BRL and its specifically targeted PNAs to BBI is simplified by web-page links, which are easy to follow for the reader with a modest knowledge of computer use.

DEFINITIONS

Amplification of an oligonucleotide or an entire gene: See polymerase chain reaction.

cDNA: Copy DNA, as by PCR or RT-PCR.

DNA probe: An oligonucleotide sequence that complements a sequence (usually of a gene) in or from an organism. Here, DNA is used generically in the description of probes.

dsDNA: Double-stranded DNA, as in the double helix.

endonuclease: An enzyme that hydrolyzes (breaks) an oligonucleotide chain between particular bases only; consequently, the pattern of pieces of DNA (oligos) generated by the action of endonuclease on DNA of a particular organism is reproducible.

Genome: The entire DNA complement [gene(s)] of an organism; this includes the genetic information in viruses.

Morpholino oligo: An oligo containing the morpholino analog of the conventional backbone (Fig. 1a).

Nucleoside: Molecule containing a purine or a pyrimidine base linked to a pentose sugar.

Nucleotide: A phosphorylated nucleoside.

Oligonucleotide (also termed oligos): Usually a sequence of DNA or RNA with a phosphate backbone (Fig. 1b), but may have a sulfate, peptide, or morpholino backbone in place of a phosphate one, to reduce or eliminate oligo degradation by nucleases.

PCR: See polymerase chain reaction.

Phosphorothioate oligo: An oligo (usually a probe) containing S in place of P (Fig. 1c).

PNA oligomer: Peptide nucleic acid oligo (Fig. 1d); manufacturers include Boston Probes (www.bostonprobes.com); the Danish company; Pantheco (www.pantheco.com), and Research Genetics (www.resgen.com). These, like morpholino analogs, resist nuclease digestion.

Polymerase chain reaction: The method for producing, in vitro and fairly rapidly, millions of copies of a specific segment of DNA or RNA (amplification). The sequence of the ends of the portion to be copied must be known so that the primer can be annealed to the denatured oligo to be copied. An excellent source for PCR applications is www.eppendorfsi.com/application.html.

Primer: The segment of synthetic oligo that is added to one end of the DNA or RNA to be copied. The denatured oligo target is annealed with the primer, and DNA polymerase then adds complementary nucleic acids until the full copy is produced. See Ref. 1 for figures and further explanation.

Reverse transcriptase (RT): The enzyme from RNA viruses that codes (cDNA) from RNA.

Fig. 1 Dinucleotide structures (as found in respective dinucleotides). (a) morpholino analog; (b) normal DNA or RNA; (c) phosphorothioate analog of DNA; (d) peptide nucleic acid.

Sense strand: In dsDNA, the strand that codes for the protein that is generated from it. The other strand is complementary, and protects the sense strand.

ssDNA: Single-stranded DNA, as contrasted with dsDNA

Target of an oligonucleotide probe: Usually ribosomal RNA (rRNA), which (with uridine in place of thymine) is the complement to the sense strand of the dsDNA in the double helix.

Triplet code: Although the coding for the amino acid sequence of proteins is by sets of three nucleotides in the DNA, the actual blueprint for protein synthesis is in RNA transcribed from the DNA. For example, in the RNA copied from a gene, UAU (uracil–adenine–uracil) or UAC (C is cytidine in the second uracil) are triplet codes for tyrosine.

ABBREVIATED BACKGROUND

Every characteristic of an organism (single-celled or multicelled) is dictated by its genome. For example, all metabolic processes are determined by enzymes that are encoded in the genome (some enzymes are imported and/or exported from a microbial cell in plasmids, which are small closed DNA loops of genes separate from the microbial chromosome). In some viruses, the genome is ssDNA or RNA, but in the majority of organisms, including microbes, it is dsDNA. The double helix of dsDNA contains a sense strand, which carries the sequence of the nucleotide triplet codes that characterize the amino acid sequence of the protein they code for. The other nucleotide strand in dsDNA is complementary to the sense strand and stabilizes it (Fig. 2).

Although some segments of the DNA in a microbial cell provide information that can identify the cell to species, there is only a single copy of DNA per cell. There may be 10^4 or more copies of the 16S rRNA per cell involved in the production of various proteins (usually enzymes) for use by the cell. The rRNA of molecular weight 16S (designated as Svedberg units in the ultracentrifuge) provides regions that are suitable for identification of the microbe to species (Fig. 3).

Therefore, if the 16S rRNA of an organism can be made available to oligo probes, usually by opening the organism in some way, it is possible to see whether the rRNA of the microbe anneals (forms a duplex) with the labeled synthetic oligo probe of known sequence and identity. There are several ways of doing this. However, in my view, unless the genus of the organism is known with reasonably good probability, this method is inordinately expensive in the use of labeled probes.

Fig. 2 Schematic of base pair in dsDNA (above) and acridine orange (AO) (below). The AO intercalates between sequential base pairs, extending the phosphate backbone.

Fig. 3 Extrachromosomal ribosomes in a bacterium or fungus that contain 16S rRNA.

APPROPRIATE USE OF OLIGO PROBES

In my view, before labeled probes are put to use for the identification of an unknown, the organism should be tentatively identified. Conventional (but effective) hand methods derived from *Bergey's Manual* can be painfully slow. The fatty acid methyl ester (FAME), technique reference (6), or one of the methods outlined in (7) are usually quite accurate and sufficiently rapid if the patient is not in extremis. Also, it is wise to remember that conventional bench methods (e.g., *Bergey's*) are dendritic, and for microbiologists lacking considerable experience, an error in any of the sequential steps may result in error in the identification. The earlier a mistake is made in a dendritic pattern, the greater the error in identification (i.e., if a bird's nest is near the end of a limb on the north side of the tree and one chooses to climb on a limb on the south side of the tree in search of the nest, one will be right about the nest being above ground, but remote from the objective).

If preliminary information is available (e.g., indicators of pathogenicity), the most cost-effective and reliable approach may be to go directly to probes. Also, probes make best sense in widespread screening for specific diseases such as tuberculosis. In disease states, whether in humans, animals, or plants, symptoms may indicate the presence of one or a few pathogens. In such instances, the use of probes directly is sensible and economical. Machine identifications, based not on genomic but on chemical analyses, become confirming and often unnecessary.

Probes, depending on the oligo target in the organism, are for practical and definitive purposes. Errors with nongenomic machines (e.g., FAME profile by GC, or mass spectrometry/fuzzy logic profile, etc.) are because the organism sought is not in the machine library, or the concentration of key chemicals (almost always oligonucleotides, oligosaccharides, and/or FAME from the organism) is too low (insufficient cells or incomplete extraction).

For some very slow-growing organisms such as *Mycobacterium tuberculosis* and *M. leprae*, sufficient organisms may be present for analysis by probe in the sample fluid or tissue, in which case the use of penetrant aids such as DMSO facilitates the exposure of chemiluminescent-labeled oligo probes to the genome of the organism. The DNA of the organism then fluoresces under ultraviolet epi-illumination. A marvelous tutorial on probe labeling is available at www.jic.bbsrc.ac.uk/staff/pat-heslop-harrison/methods/probe.html. The method with fluorescent-labeled probes when applied for the detection of cancers or genetic effects, to human or animal genes in tissue, is called fluorescent in situ hybridization (FISH).

DEFINED OLIGOS ON MAGNETIC BEADS

Blotting and related methods have been discussed in a previous review (1). A very rapid technique employs specific oligos immobilized on Dynal[®] magnetic beads. The special advantage is that the beads, covalently coupled to particular oligo sequences (or antigens, antibodies, or other binding entities), can be mixed in a nonmetallic container (e.g., test tube) with a solution or suspension so as to react even with very dilute targets (organisms, especially viruses). The beads are then concentrated simply by placing a magnet against the side of the container. The original solution, less the bead-reacted targets, is then removed and the beads rinsed in situ. An oligo-magnetic bead method is outlined in (7). The recovery of mRNA (terminal polyA sequence) is with poly dT beads (8).

The basic magnetic-bead patent appears to be the property of Dynal, but Clemente Associates (formerly Quantum Magnetics, Madison, CT) produces Ni-bearing magnetic particles of 3- to 5- μ m diameter for performing what they refer to as "magnetic chromatography," of cells, proteins, or both. Qiagen (Valencia, CA, and other locations) markets histidine-labeled Ni-containing agarose magnetic beads. Bangs Laboratories (Fishers, IN) also produces 2- μ m diameter beads with surface carboxyl groups for the coupling of binding ligands. Seradyn (Indianapolis, IN) uses beads for DNA isolation. All of these can bear oligo probes. CPG, Inc. (Lincoln Park, NJ) offers streptavidin magnetic porous glass for the binding of biotinylated molecules for a variety of oligo-probe-related purifications of cells, noncellular particles, and macromolecules, including DNAs and RNAs.

Nonmagnetic beads of a variety of matrices, ready for coupling by various chemistries to oligos, antibodies, antigens, or what-have-you, are available for column or suspension applications from Polymer Laboratories (www.polymerlabs.com).

THE POLYMERASE CHAIN REACTION (PCR) AND THE DETECTION OF MICROBES

If a dozen copies of a pathogenic DNA virus are present per milliliter or gram in body fluid or beef tissue intended for sale, inoculation of the suspect source material into cell culture or in a test animal for analytical testing is a very lengthy, expensive process. It is unrealistic for use in the food industry or in a hospital, as are many other tests. If we seek particular viruses (e.g., rabies), the most rapid, practical, and effective means of detecting the virions is the PCR.

The general sequence of events in performing PCR is shown in Fig. 4. The primer used is an oligo specific to the organism to be detected. Commencing with the DNA recovered from one or several organisms, the multiplication of genomic material can be 10^7 -to 10^8 - fold in 35–90 min. By comparison, growing the virions in cell culture to equivalent numbers (to allow monoclonal antibody type analyses) usually requires 48 h or more. In cases where life hangs in the balance of an accurate analysis, those hours may be critical.

Even with bacterial or fungal pathogens, the time required to generate sufficient genomic material for analysis by PCR is 35–45 min but 24–48 h in conventional culture on an appropriate nutrient medium. Some useful background information on PCR is provided in the Eppendorf web page (www.eppendorphi.com/

applications.html). The reader is also referred to the previous version (1), which provides details in a somewhat different manner. Primers (DNA probes needed for PCR) have been described particularly well by Steve Rozen (Whitehall Institute, MIT Center for Genomic Research, Cambridge, MA). The material he has developed is available, gratis, at www.genome.wi.mit, which appears to be difficult to recover. HIV primers are shown at www.appliedbiosystems.com/pc/catalog/pg25.html.

Reverse transcriptase PCR, (RT-PCR), runs the normal RNA to DNA sequence backward. Reverse transcriptase is an enzyme found in RNA viruses and, when added to a solution of RNA, deoxynucleotides, reverse transcriptase, etc., allows one to produce the DNA equivalent to the RNA recovered from an organism. The cDNA (DNA produced from RNA) recovered in sufficient amounts can then can be "clipped" using a well-characterized endonuclease and a cDNA "fingerprint" generated for comparison with the fingerprints of known RNA sources. Automated systems for doing this can be purchased from Qualicon, a DuPont spinoff (info@qualicon.com) or from Applied Biosystems (www.appliedbiosystems.com/ab/about/mm/microseq/microseq500/).

IMMOBILIZED OLIGOS OR GENES IN ANALYTICAL ARRAYS

As reported in the previous version of this article (1), immobilized oligos in arrays (e.g., in the wells of microtiter plates or on glass slides) are used in the detection of cancer and precursor stages (e.g., mutations), in addition to drug screening of the interactions of candidate drugs (free) with human or animal gene sequences (immobilized). A tutorial on microarray technology is presented by Virginia Tech and the Forest Biotechnology Group at the North Carolina State University (9).

To provide the reader with an appreciation of the flexibility possible with arrays, I consider the possibilities inherent in combinatorial chemistry (10). One possible approach involves the extraction of the gene of each of hundreds of bacterial species, grown as axenic (pure) cultures. In each of the wells of microtiter plates molded from polyethylene-co-acrylic acid, segments of the gene of a single bacterial species (prepared when the DNA from the cells of a particular colony are "clipped" with a known endonuclease) are added and immobilized to the bottom of the plate via the 3'-OH. A good immobilization system is the triazine method for coupling linear microbial DNA strands (Fig. 5). To each of these plates, bearing (for example) ca. 100 wells and the genomes of 100 human

Fig. 4 Sequence of events in the PCR.

microbial pathogens, is added one of the many varieties of possible synthetic oligos intended for test as potential drugs (limited mixtures, each unpurified but reproducible), each with a low toxicity label, preferably chemiluminescent rather than radioactive.

The drugs (e.g., PNAs) and immobilized microbial genomes are allowed a reaction time, rinsed, and then examined (automatically or by eye,) for retention of the synthetic candidate drugs by segments of the genomes of the various pathogens. In this way, it is possible to screen

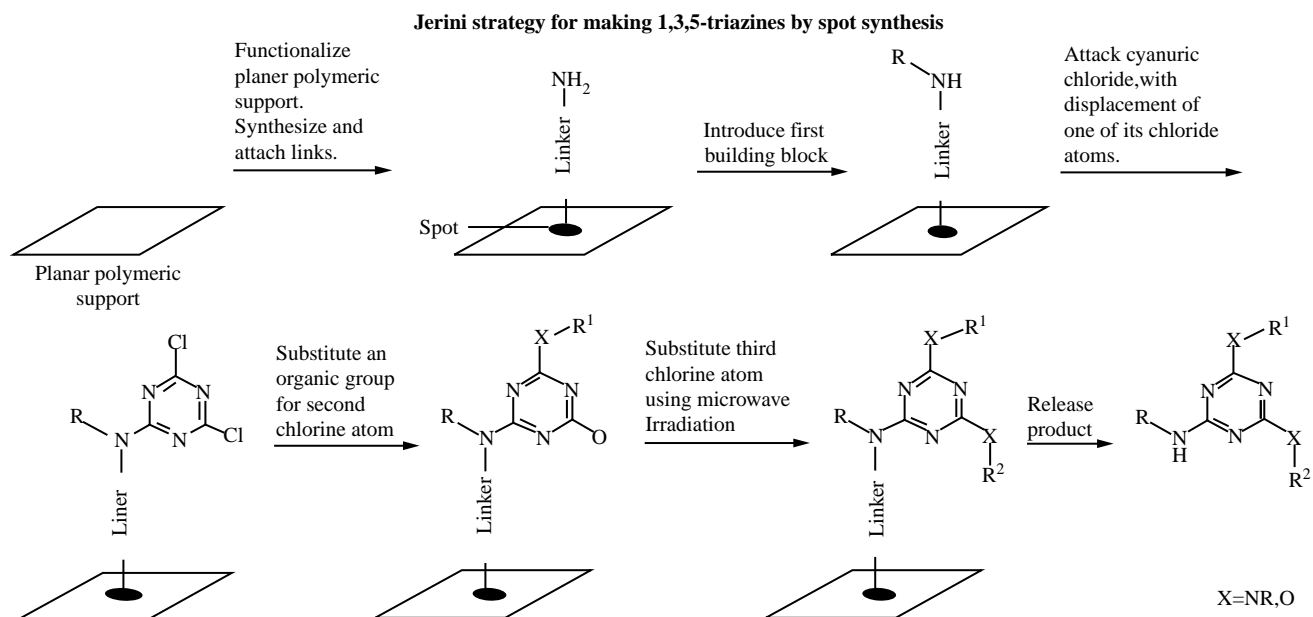

Fig. 5 Coupling microbial ssDNA or RNA or analogs via triazine to wells in a microtiter plate.

candidate oligos for specific binding to immobilized genomes of known organisms, even if gene sequences of the pathogens are unknown, and the precise sequence that binds to a given pathogen's genome is known only with modest accuracy.

In cases where this combinatorial-type approach to new product development appears promising, it can be automated, all or in part. Such systems are in widespread use in a variety of applications in the pharmaceutical industry. The example given is a variation of the method known as combinatorial chemistry.

A variation on this method has been proposed by the U.S. National Institute of Environmental Health Sciences to evaluate chemicals as potential human toxins. Human genes, immobilized on microtiter-type plates, are exposed to known and unknown toxicants, with a view to seeking similarities in gene-binding patterns (11). Origene (Rockville, MD), Qiagen (Valencia, CA, and other sites), CCS Packard (Meriden, CT), and many others may be added to the list of array-type manufacturers/distributors listed in Table 3 in Ref. 1.

SPECIFIC OLIGO PROBES AS ANTIMICROBIALS

The DNA of a cell must be copied if the cell is to reproduce. Also, certain enzymes are required for a cell to metabolize and function (as contrasted with the dormant

state), and these are usually made in the cell as needed. Therefore, an antisense probe that reacts with, for example, a critical RNA in the cell, may effectively render the cell dormant. One can envision this in vitro and in vivo. But oligonucleotides are subject to degradation by nucleases which, depending on their specificity, clip a nucleotide at certain base sequences, usually rendering the oligo less functional or nonfunctional. (This is also how DNA is clipped in the process of generating "fingerprints.")

If a species-specific antisense oligo probe can be made resistant to enzymic degradation, and if it can readily enter a microbe, the probe not only identifies the organism, but also may shut down the metabolic potential of the cell (11). Antisense PNA oligos appear to meet these requirements and bind to sense with a lower dissociation constant (K_d) than does the phosphate-backbone antisense. PNA antisenses have the potential for use as very specific, low-toxicity microbicides for in vivo applications (12). The peptide analogs of DNA probes are protected by appropriate patents (13). The text of choice is from the same authors and others (14).

Boston Bioprobes is producing PNAs for oligo research, development of diagnostics, testing of foods, and the environment. Perkin-Elmer (now largely renamed Analytical Biosystems, Foster City, CA) has invested with BBI and will participate in PNA technology.

ANTISENSE PROBES AS THERAPEUTICS

The primary target of antisense probe studies is the ongoing cell proliferation in all cancers.

Cancerous cells are not functional in, for example, gas transport in the lung. Like viruses, their anthropomorphized *raison d'être* is only to reproduce, not to perform a service for the organism of which they are a part. On the other hand, normal cells have a finite lifetime and must occasionally be replaced.

The toxicants used in conventional chemotherapy and radiation not only kill a substantial proportion of the cells that are reproducing rapidly but also tend to destroy stem cells in the bone marrow and circulating plasma, which gives rise to the panoply of red cells, white cells, and platelets that are essential to a survival free of dialysis machines and other elaborate supports. For this reason, patient-sourced (autologous) stem cells (CD34+),

hopefully cancer-free, are recovered from the patient prior to radiation treatment or chemotherapy (or both) as “heroic” cancer therapy. The recipient of massive “chemotherapy,” or radiation (or both), dies unless those healthy stem cells (removed from the patient prior to treatment) are injected intravenously (they find their way to the marrow) and replace the essential cells that chemotherapy or radiation has destroyed.

In addition, although chemotherapy and radiation may “cure” a patient, the once-healthy cells that are not killed may be mutated in critical portions of the genome. It is fairly common that patients receiving “heroic” therapy develop new tumor sets 20 years downstream of the initial therapy. Ultimately, the exposure to these unselective toxicants that saved the patient may eventually kill the patient. (“The therapy was successful, but the patient died.”)

In theory, the beauty of antisense is that an antisense oligo probe does not damage all types of cells at random,

Fig. 6 Small organic molecules that interact with DNA and/or RNA and when excited with one wavelength of light, fluoresce in another. (a) acridine orange; (b) Hoechst 33342; (c) mithramycin; (d) chromamycin A3.

and does not induce mutations. Antisense shuts down the propagation of some cells, and not others. Antisense therapy is distinct from gene therapy, in which a missing or malfunctioning gene (e.g., human clotting factor VIII gene in most hemophiliacs) is placed in autologous cells and returned to the patient.

Professor Eric Wickstrom (Kimmel Cancer Center, Thomas Jefferson University, Philadelphia, PA) has done some excellent work in mouse models on antisense and Burkitt's lymphoma, rabies virus, and the human *cMYC* oncogene, to name a few systems. His group employs phosphorothioates, PNAs, and other variations on antisense. His web page is at www.kcc.tju.edu/staff/wickstrom and several of his recent papers (15, 16) and his book (17) should be of interest to the reader interested in antisense. His patents on the synthesis (18) and introduction of antisense into cells (19) are germane.

Some of Wickstrom's work points to the issue of antisense entry into a cell. At least one company, Gene Therapy Systems, is devoted to this (www.genetherapy-systems.com).

SMALL, NONSPECIFIC ORGANIC PROBES THAT LOCATE INTACT DNA

Some organic molecules have a high affinity (low K_d) for DNA and are stoichiometric but not specific in the manner of a complementary oligonucleotide. For example, acridine orange (AO; Fig. 6a), is planar and intercalates between the paired sets of H-bonded base pairs (A-T, G-C) in dsDNA (Fig. 2). Where AO penetrates into a cell and "reacts" with the dsDNA, the cell emits green light when excited with blue. AO also reacts with ssDNA or RNA by stacking on the charged phosphate of the backbone; ssDNA fluoresces in the red.

Benzamides such as Hoechst 33342 (Fig. 6b) bind to A-T-rich regions in the small groove of dsDNA. When sufficient dye is excited with blue light, light emission is red. The antibiotics mithramycin and chromamycin A3 (Fig. 6c and Fig. 6d) bind to G-C regions of DNA.

These small molecule probes of DNA (ds and ss) and RNA do not identify organisms, but indicate probable viability because the genome is intact. When cells in suspension or on a slide are stained and examined under a UV-epi-illuminated microscope or in a flow cytometer, with or without cell sorting, then viability can be estimated with fairly high precision and accuracy. This and related topics are developed in (7), and in portions of the molecular probes pages (www.probes.com), which the reader may find particularly useful.

DISSOLUTION AND DISSOLUTION TESTING

James L. Ford

Liverpool John Moores University, Liverpool, United Kingdom

Ali R. Rajabi-Siahboomi

Colorcon Limited, Kent, United Kingdom

INTRODUCTION

Dissolution tests are one of the tests most used in the characterization of drugs and in the quality control of dosage forms. During the late 1960s it became recognised that dissolution data should be determined by studying the rate at which dosage forms allow their formulated drug to dissolve. Subsequently, dissolution tests for six products were introduced into the USP 18 (1969). This increased to about 600 tests in the USP 24, which also includes drug-release requirements for modified release products and transdermals.

Although dissolution tests are mainly used as quality control methods to ensure end-product or batch-to-batch consistency and to identify good and bad formulations, dissolution data may also be correlated with in vivo activity. Dissolution tests become especially important if dissolution is the rate-limiting step in drug absorption. Dissolution tests are, therefore, used to confirm compliance with compendial specifications and are needed as part of a product licence application. Additionally they are used during product development and stability testing as part of the specification for the product. No universal dissolution test has been designed that gives the same rank order for in vitro dissolution and in vivo bioavailability from different formulations and batches.

MATHEMATICAL CONCEPTS OF DISSOLUTION

Dissolution of Particles

Eq. 1 is one of the oldest expressions used to describe the dissolution process of a particle:

$$\frac{dW}{dt} = \frac{D}{h} S(C_s - C_t) \quad (1)$$

where dW/dt is the rate at which a material dissolves across a surface S at a time t ; $C_s - C_t$ is the concentration gradient

between the concentration of solute in the stagnant layer (thickness h and immediately adjacent to the dissolving surface) surrounding the dissolving particles, and is assumed to be equal to the difference between the saturated solubility of the drug (C_s) and the concentration of the solute in the surrounding medium at time t (C_t). The parameter D is a function of the diffusion coefficient of the solute molecules. Maximum dissolution rates are predicted when $C_t = 0$. Consequently, as C_t increases, the dissolution rate decreases. The parameter D is also dependent on $C_s - C_t$. Such conditions, where dissolution is followed by absorption of the drug, an in vivo situation, are described as sink conditions (i.e., $C_t < 0.1 C_s$). In vitro systems should ideally maintain a sink condition and the dissolving solid should be tested in fresh solvent.

In Eq. 1 the parameter D is temperature dependent. Consequently, both the temperature of the dissolution fluid and its viscosity (which is also temperature dependent) should be carefully controlled. In addition, the presence of electrolytes and changes in pH may influence the diffusing species by altering their ionization. Such factors imply that dissolution fluids should be as simple as possible.

The constraints imposed by sink conditions may be overcome using various approaches. It may be accepted that non-sink conditions apply and that incomplete dissolution will occur. Alternatively, corrections may be made by increasing the volume of the dissolution fluids, removal of the dissolved drug by partition from the aqueous phase of the dissolution fluid to an organic phase either above or below the dissolution fluid, addition of selective adsorbents to remove the dissolved drug, addition of a water-miscible solvent to the dissolution media to increase drug solubility or removal of dissolved drug, using a flow-through system.

Dissolution of a Mono-Dispersed Powder

Dissolution processes of multiparticulate systems where the specific surface area decrease during the dissolution,

Fig. 1 Dissolution data for a hypothetical solid plotted as cumulative amount released (right axis) and after cube-root-law data treatment (left axis).

may be described by the Hixson and Crowell (1) cube root law in Eq. 2:

$$W_0^{1/3} - W^{1/3} = Kt \quad (2)$$

where W_0 represents the original mass of drug, W is the amount of remaining drug at time t , and K is the dissolution rate constant. Fig. 1 represents a typical plot where a straight-line release exists throughout the substantial period of the dissolution. The cube-root law assumes several factors, including a constant diffusion layer thickness, isotropicity of the sample, an independence of solubility of particle size, smooth surfaces, and sink conditions. Modifications of the equation are required for non-sink conditions and polydisperse systems; for example, Lai and Carstensen (2) derived shape factors to modify cube root behavior. In reality, dissolution from multiparticulate systems requires more complex mathematical approaches to dissolution. Associated problems include correctly assigning the particle size distribution to the powders, the fact that small particles have higher solubilities than larger ones, and accounting for changes in both the size and the number of particles during dissolution.

Dissolution of Disintegrating Tablets and Capsules

The development of theories of dissolution from disintegrating tablets and capsules becomes very difficult because disintegration produces vast changes in surface area. Attempts have been made to develop models to describe dissolution rates from tablets, using complex mathematical approaches (3, 4).

Dissolution of Nondisintegrating Tablets

For systems where drug release involves the dissolution of a soluble drug at high concentrations from an insoluble matrix, the Higuchi (5) equation adequately describes release rates (Eq. 3):

$$\frac{W_r}{t^{1/2}} = 2W_0 \frac{S}{V} (D/\pi\tau)^{1/2} \quad (3)$$

where W_r is the amount of drug dissolved in time t ; W_0 is the dose of the drug; S is the effective diffusional area; V is the volume of the hydrated matrix; D is the diffusion coefficient of the drug in the hydrated matrix; and τ is the tortuosity of the matrix. An analogous equation was developed for drugs of limited water solubility (6).

It is not the aim of this article to evaluate formulation aspects that may influence dissolution of drugs from dosage forms. However, it suffices to mention that dissolution rates from unformulated powders or tablets may be increased or decreased according to many factors, including salt selection, the presence of surfactants, polymorphic modifications, and the use of water-soluble carriers as in solid dispersions.

Having identified some of the important criteria and models for dissolution, let us examine some of the apparatus used to measure dissolution rates.

DESIGN OF APPARATUS

The ideal features of a dissolution apparatus are (7):

1. The fabrication, dimensions, and positioning of all components must be precisely specified and reproducible, run to run.
2. The apparatus must be simply designed, easy to operate, and useable under a variety of conditions.
3. The apparatus must be sensitive enough to reveal process changes and formulation differences but still yield repeatable results under identical conditions.
4. The apparatus, in most cases, should permit controlled variable intensity of mild, uniform, non-turbulent liquid agitation. Uniform flow is essential because changes in hydrodynamic flow will modify dissolution.
5. Nearly perfect sink conditions should be maintained.
6. The apparatus should provide an easy means of introducing the dosage form into the dissolution medium and holding it, once immersed, in a regular reliable fashion.
7. The apparatus should provide minimum mechanical abrasion to the dosage form (with exceptions) during

the test period to avoid disruption of the microenvironment surrounding the dissolving form.

8. Evaporation of the solvent medium must be eliminated, and the medium must be maintained at a fixed temperature within a specified narrow range. Most apparatuses are thermostatically controlled at around 37°C.
9. Samples should be easily withdrawn for automatic or manual analysis without interrupting the flow characteristics of the liquid. In the latter case, efficient filtering should be achieved.
10. The apparatus should be capable of allowing the evaluation of disintegrating, nondisintegrating, dense or floating tablets or capsules, and finely powdered drugs.
11. The apparatus should allow good interlaboratory agreement.

There are two principal types of apparatus design. One is based on limited volume that is constrained to the size of the container used. The second type uses a continuous-flow cell to house the dosage form and permits constant replenishment of the dissolution fluids.

COMPENDIAL APPARATUS WITH FIXED VOLUMES OF DISSOLUTION FLUID

The general principle of dissolution tests is that the powder or solid dosage form is tested under uniform agitation, which is accomplished by either using a stirrer inside the apparatus or rotating the container holding the dosage form (e.g., a basket). Two general methods are currently included in the USP 24 (8) and the BP 2000 (9) to measure dissolution from tablets and capsules. In apparatus 1, the dosage forms are enclosed in a basket; in apparatus 2, agitation is provided by means of a paddle. Each apparatus is a limited volume-type apparatus.

Basket Apparatus

The basket method was first described in 1968 by Pernarowski et al. (10). A container, the basket, constrained the enclosed tablet or capsule, allowed for fluid change and could be used either in continuous flow or in restricted volume modes. This gradually evolved to the USP 24 (8) and BP 2000 (9) apparatus 1—the rotating basket apparatus (Fig. 2). The dimensions are taken from the USP 24, although those given in the BP 2000 are similar. The apparatus consists of a motor, a metallic drive shaft, a cylindrical basket, and a covered vessel made of glass or other inert transparent material.

Fig. 2 The basket stirring element of the United States Pharmacopeia 24. (From Ref. 8.)

The latter should be made of materials that do not sorb or react with the specimen being tested. The contents are held at $37 \pm 0.5^\circ\text{C}$. There should be no significant motion, agitation, or vibration caused by anything other than the smoothly rotating stirring element. Ideally, the apparatus should provide observation of the stirring element and specimen. The vessel is cylindrical with a hemispherical bottom and sides that are flanged at the top. It is 160–210 mm high and has an inside diameter of 98–106 mm, and a nominal capacity of 1000 ml. Other sizes are described for 2 and 4 L capacity vessels. A fitted cover may be used to retard evaporation but should provide sufficient openings to allow ready insertion of a thermometer and allow withdrawal of samples for analysis. The shaft is so positioned that its axis is no more than 2 mm at any point from the vertical axis of the vessel and should rotate smoothly, without significant wobble. The shaft rotation speed should be maintained within $\pm 4\%$ of the rate specified in the individual monograph. The shaft has a vent and three spring clips or other suitable means to fit the basket into position. Each should be fabricated of stainless steel, type 316 or equivalent. Welded seam, stainless steel cloth (40 mesh or $425 \mu\text{m}$) is used, unless an alternative is specified. For testing, a dosage unit is placed in a dry basket at the beginning of each test. The distance

Fig. 3 Typical apparatus set up for basket and paddle apparatus.

between the inside bottom of the vessel and the basket is 25 ± 2 mm. Typical arrangements for the apparatus are shown in Fig. 3.

Although the basket apparatus in the BP 2000 and USP 24 are similar and have a common design, considerable changes have taken place since basket apparatuses were first included in official monographs. The USP 18 (11) described a cylindrical vessel with a slightly concave bottom. No precise specifications were given for the concave bottom and differences in tolerances supplied by different manufacturers were common. Consequently, statistically different dissolution rates could be obtained when determined using containers obtained from two different manufacturers (12). Flask shape had affected the hydrodynamics of systems and consequently it was considered better to have flasks of uniform hemispherical shape. The flat-bottomed flask described in the BP 1980 (13) alleviated the problems of manufacturing tolerances in vessel shape. Irrespective of apparatus design, there are still several potential problems. The wire basket corrodes following exposure to acidic media; the basket method gives poor reproducibility due to inhomogeneity of the agitation conditions produced by the rotating basket; and clogging of the basket can occur due to adhering substances. Additionally, particles can fall from the rotating basket and sink to the bottom of the flask where they will not be subjected to the same agitation as that inside the basket.

Paddle Apparatus

An apparatus described by Levy and Hayes (14) may be considered the forerunner of the beaker method. It consisted of a 400 ml beaker and a three-blade, centrally placed polyethylene stirrer (5 cm diameter) rotated at

59 rpm in 250 ml of dissolution fluid (0.1 N HCl). The tablet was placed down the side of the beaker and samples were removed periodically.

In the pharmacopoeial apparatus 2—the paddle apparatus method—a paddle replaces the basket as the source of agitation. As with the basket apparatus, the shaft should position no more than 2 mm at any point from the vertical axis of the vessel and rotate without significant wobble. The specifications of the shaft are given in Fig. 4. A distance of 25 ± 2 mm between the blade and the inside bottom of the vessel is maintained during the test. The metallic blade and shaft comprise a single entity that may be coated with a suitable inert coating to prevent corrosion. Again typical arrangements for the apparatus are shown in Fig. 3. The dosage form is allowed to sink to the bottom of the flask before rotation of the blade commences. Sinkers are recommended to prevent floating of capsules and other floatable forms. A small, loose piece of nonreactive material (e.g., a few turns of wire helix) may be attached to the dosage form. Soltero et al. (15) thoroughly examined the influence of sinker shapes on dissolution rates obtained from gelatin capsules. Although a stainless steel helix is officially recommended, alternative shapes can greatly affect the dissolution rates.

Data Presentation and Interpretation

The data collected during dissolution tests will, especially at the developmental stage, be presented as dissolution profiles (Fig. 5) whereby the amount released is plotted as a function of time. It is common practice to monitor drug release at several points or where possible continuously until 100% of the dose is dissolved and dissolution profiles showing drug release against time can be produced. Values equivalent to the times for 10, 50, 70, or 90% drug release are often cited ($t_{10\%}$, $t_{50\%}$, $t_{70\%}$, or $t_{90\%}$). The dissolution profiles from tablets and capsules are often sigmoidal in shape.

Pharmacopoeias generally do not require a dissolution profile to be determined but do specify that a certain amount of drug must dissolve within a specified time. Should a single time specification be stated, the test may be concluded in a shorter time if the requirement for a minimum amount dissolved is met. If two or more times are specified, then the samples should be withdrawn with a tolerance of $\pm 2\%$ of the stated time. For Digoxin Tablets B.P. (9), when there is more than one tablet per test, all six replicate runs should release at least 75% of the stated amount within 60 min.

The USP 24 (8) assesses dissolution in three stages. Should the specifications be met at either of the initial two stages, there is no requirement to proceed to later stages. In stage 1, six units are tested. To pass the test, each unit, at the specified time, should have $Q + 5\%$ in solution where Q is the amount of dissolved active ingredient expressed as a percentage of the labelled content and 5% is the percentage of labelled content. Failure at stage 1 requires a second stage test on an additional six units. To pass the test at this stage, the average content dissolved, from the combined two

Fig. 5 Dissolution profiles of a hypothetical dosage form indicating the determination of $t_{50\%}$, $t_{70\%}$, and $t_{90\%}$ values.

stages, should be equal to or greater than Q with no unit being less than $Q - 15\%$. Failure leads to stage 3 where a further 12 units are tested. These results are combined with the results from the previous stages. The average of the total of the 24 units thus tested should be equal to or greater than Q . No more than two units should be less than $Q - 15\%$ and no unit should be less than $Q - 25\%$.

Sample Collection Procedures

The USP 24 (8) and the BP 2000 (9) state that samples should be drawn from a zone midway between the surface of the dissolution medium and the top of the rotating basket or blade, not less than 1 cm from the vessel wall. A volume of media equal to the volume of sample withdrawn should be replaced or compensated for by calculation. Samples removed should be filtered. Any substance released from the filter should contribute no significant absorption to the active ingredient in solution or interfere with the assay. No extractable materials interfering with the analytical procedures should be released. The filter pore size should not be greater than 1 μm . When capsule shells interfere with the analysis, the contents of a minimum of six capsules should be removed as completely as possible and the shells dissolved in the dissolution medium. This allows calculation of correction factors, which should be no greater than 25% of the labelled content.

Factors That May Influence Dissolution

Both the BP 2000 (9) and the USP 24 (8) give considerable guidance about external factors that may influence dissolution. This section highlights some of the more important factors.

Vibrations

No part of the assembly, including the environment in which the assembly is placed, should contribute significant motion, agitation, or vibration beyond that caused by a smoothly rotating element. There is little doubt that excessive vibration of the dissolution apparatus considerably increases dissolution rates. Therefore, to minimize the effects of vibration, the distance from the dissolution motor to the stand supporting it and the distance from the rotating basket to the point connecting the shaft to the dissolution motor should be specified (16). Vibrations may arise from various sources, including water bath and pump.

Shaft

Many problems associated with variations in the dissolution rate are caused by misalignment. Limits should be set on shaft eccentricity. Minor changes in physical alignment of the paddle may produce large variations in results.

Vessel

The use of a hemispherical flask allows some variation in construction. Minor changes in vessel shape may considerably alter the dissolution rates determined by the paddle method (17). Glass vessels with an inside bottom flatter than specified gave a high bias in dissolution rates and those with an inside bottom of steeper curvature gave a low bias. Such bias is associated with the different hydrodynamics created by the different shapes. Plastic vessels provide more perfect hemispheres than glass vessels and their shape is more reliable and should be preferred to glass containers provided the drug does not sorb to them and that the dissolution fluid does not interact with the plastic (17). However, plastic containers are not without their problems. During dissolution, some tablets may become more centred in glass vessels than in plastic vessels, which is probably attributable to friction between the tablet and the wetted vessel surface being greater for plastic than for glass (18).

Sampling procedures

Flow through facilities usually allow ultraviolet (UV) analysis of drug dissolved or collection of samples for subsequent analysis (Fig. 3). Filtering must be accomplished before analysis to prevent insoluble excipients or dissolving drug particles from passing through the beam. Filters remove solid particles prior to assay at the stage of sample removal, reduce turbidity problems caused by undissolved drug and excipients, and help eliminate spurious results caused by particles dissolving following removal.

A sampling probe used for continuous sampling must not disturb the hydrodynamics of the system. When continuous monitoring is accomplished by flow-through systems, the flow rate should not be too high or some of the suspended drug will adhere to the filter, resulting in a percolation effect and artificially high estimates of the amount of drug released. Care should be taken with automatic flow methods so that tube length is kept to a minimum to reduce the amount of fluid in the tubing. Excessive amounts will produce long lag periods before dissolved material is transported from the dissolution vessel to the analyzing cell.

Adsorption of the drug onto the filter should be avoided and the release of isooctylphenoxypolyethoxyethanol, which is often included in the membrane filters as a wetting agent, may be a potential problem (19). This surfactant has significant absorption in the 220–240 nm wavelengths. Selection of a suitable pore size is important. Adsorption onto filters of frusemide was increased by using filters of decreasing pore size but of the same diameter (20). Replacement of sampled fluid must be by fluid of the same temperature as that inside the dissolution vessels. Recent developments have focused on the possibility of utilizing a UV-fiber-optic probe to pipe light in the dissolution medium where a spectrophotometric assay *in situ* through fiber-optic light guides may be carried out (21).

Temperature control

The USP directs that the thermometer should be removed before the test and that the temperature should be checked periodically. The dissolution fluids should be maintained at $37 \pm 0.5^\circ\text{C}$. Even slight temperature variations may have a significant effect on tablet dissolution.

Deaeration of dissolution medium

The levels of dissolved gas are not specified in either the BP 2000 (9) or the USP 24 (8); each states that media should be deaerated before use. By testing the dissolution of prednisone tablets in water that had been presaturated with air, Cox et al. (22) showed that the media must remain unsaturated during the test. Higher initial air content resulted in increased percentages of drug dissolved during the paddle method. Air bubbles, in the media that contained higher levels of air, attached to particles of the disintegrating tablets owing to sorption of air. The particles did not sink to a mound at the bottom of the vessel but were suspended by the air bubbles and were, therefore, subject to greater conditions of agitation.

Failure to deaerate media used with the basket apparatus results in the clogging of the pores of the basket by air, causing different flow characteristics (19) and often a decrease in dissolution rates. This has even greater influence when gel-forming extended-release dosage forms are being tested. Bubbles attached to tablets or capsules may cause the dosage form to relocate near to the top of the basket, thereby reducing dissolution rates or amounts dissolved (19). The basket is intended to hold the tablet in a fixed position. Disintegration of the dosage form will occur in the basket and fluid must flow through the basket sufficiently to disperse the tablets and sweep dissolved drug into the bulk of the dissolution fluid.

Variation in speed of agitation

Agitation speed must be uniform throughout the test. Some motor drives result in a satisfactory mean speed but during the test will periodically slow down or speed up. Consequently, speed should be checked at the start and end of each run (19).

Standardization and Calibration

All apparatuses must be calibrated and the variables standardized and known. Experimental design in dissolution testing to examine residual variation between experimental runs and individual dissolution vessels is feasible (23). The objective is to minimize errors in experimental setup, achieved by using mean dissolution times and partial balancing. Lower coefficients of variation occur at higher hydrodynamic intensities. Dissolution tests are critical but difficult to carry out properly. Standardization should remove all variable factors. Similar problems of fluid flow exist with the current USP 24 apparatus, although the hemispherical shape will create different fluid hydrodynamics.

The USP 24 (8) specifies apparatus suitability tests, based on the operating conditions, involving the USP dissolution calibrator, disintegrating type or the USP dissolution calibrator, nondisintegrating type. The apparatus is deemed suitable if the obtained results are within the accepted range stated for that type of calibrator. Calibrators are used to show deficiencies in the equipment, for example, chain looseness, tilting of stirrer motor, excessive vibration, or misalignment of the flasks with the stirrers. Nondisintegrating calibrants are composed of 300 mg salicylic acid, whereas disintegrating calibrants contain 50 mg prednisone. The dissolution rates obtained from the calibrants should fall within established ranges at both 50 and 100 rpm.

Other Variables in Compendial Methods

The BP 2000 (9) generally specifies 1000 mL of dissolution fluid, although for digoxin tablets the volume is 600 mL water. Dissolution fluid volume is varied more in the USP 24 (8). Examples include 500 mL (alprazolam tablets), 750 mL (metyrosine capsules), and 900 mL (ampicillin capsules). The volume may additionally vary as to the strength of the preparation. Thus, for phentermine hydrochloride capsules 500 mL of medium is used if the strength is 15 mg or less, but 900 mL is used for preparations containing in excess of 15 mg. Similar volumes are used for prednisone tablets where the cut-off point is 10 mg and for cinoxacin capsules where 500 mL is

used for capsules containing 250 mg or less but 1000 mL is used for capsules containing in excess of 250 mg.

OTHER METHODS USING LIMITED VOLUMES OF DISSOLUTION FLUIDS

Many other, nonofficial methods that use limited volumes of dissolution fluids have been described. These include the rotating-disc method that measures the dissolution rate from a constant surface area, which is usually in the form of a disc (24). Intrinsic dissolution rates, which relate dissolution rate to the surface area of the dissolving drug, can easily be determined from constant-surface area discs whose areas can be very easily estimated. The rotating filter-stationary basket apparatus (25) uses a large capacity (1.5 L) glass flask containing a stationary sample basket and a rotating-filter basket.

Other apparatuses that have been evaluated for dissolution testing include the magnetic basket apparatus (26) and the commercial Bio-Dis apparatus (27). In the later apparatus, the use of vertically reciprocating tubes, sealed with mesh discs at each end to restrain the dosage form was developed. The USP 24 (8) describes, as drug release apparatus 3, the reciprocating cylinder method. The tubes are raised up and down, 9.9–10.1 cm, in dissolution fluid. The apparatus has been advocated to monitor release from pellet systems although it tended to higher values of amount released than other apparatus (27).

Limited-volume apparatus, with a finite volume of dissolution fluid, suffer from the problem that they operate under non-sink conditions, which results in limitations when poorly soluble drugs are considered. Some apparatus, previously described, may be modified by the use of flow-through systems and reservoirs to provide sink conditions by removing solvent and replacing it with fresh solvent. Continuous circulation may also be used for conditions when sink conditions are not required. The drawbacks of nonflow-through apparatus (28) include (1) lack of flexibility, (2) lack of homogeneity, (3) the establishment of concentration gradients, (4) their semiquantitative agitation, (5) the obscuring of details of the dissolution processes, and (6) their variable shear. Consequently, flow-through apparatus characterized by a dissolution cell of low volume (often less than 30 mL) and a reservoir to provide fresh solvent have been developed.

Flow-Through Apparatus

The USP 24 flow-through cell (24) may be either used in closed mode when the fluid is recirculated and, by

necessity, is of fixed limited volume, or open mode when there is continuous replenishment of the fluids. The basic components are reservoir, pump, heat exchanger, column, tablet support, filter system, and analytical method. The systems enable solvent to be taken from a suitable reservoir and passed straight through the apparatus containing the dosage form to be either assayed and removed (effluent system) or recirculated (recycling system) (Fig. 6).

The design of the pump to remove the solvent from the reservoir is crucial to the results obtained from such systems. The pump used may be either a displacement (oscillating or peristaltic) or a momentum (centrifugal) type. However, peristaltic pumps may create oscillations that result in faster dissolution rates than might otherwise have occurred. Dissolution is affected by factors such as the volumetric flow rate, the cross-sectional area of the cell, the initial drug quantity, liquid velocity, and drug concentration.

Ascending fluid flow is used. Flow-through facilities remove some of the problems associated with non-sink conditions. The material under test (tablet, capsules, or granules) is placed in the vertically mounted dissolution cell, which permits fresh solvent to be pumped (between 240 and 960 mL/h) in from the bottom. Glass beads (1 mm diameter) control the flow across the whole cross-sectional area of the cell. Cells may have diameters of 12 or 22.6 mm.

The maintenance of a controlled flow is crucial to column methods and can be influenced by the inlet system. The design of the apparatus was improved by using a holder constructed of a folded wire cross above the inlet pipe to support the tablet such that the solid is bathed in the outflow contained within a concentric column of relatively stationary liquid (29). It is common to place the tablets on such supports, but attrition (by glass beads) may encourage breakdown of the dosage form thereby increasing dissolution rates. Tablet support and consistent positioning

in the liquid flow are prerequisites for consistent results. Attempts have been made to embed the tablet in glass beads.

DISSOLUTION MEDIA

Ideally, a dissolution medium should be formulated as close as possible to that pH anticipated in *in vivo* fluids; for example, dissolution media based on 0.1 *N* HCl are used to mimic gastric pH. Simulated gastric fluid is similarly used. Food can increase the gastric pH to as high as 3–5. Many compendial dissolution fluids are at a pH near neutral despite the fact that tablets, when swallowed, will meet a lower gastric pH. The use of surfactants and enzymes may also be a coarse approximation of the intestinal fluids, although surfactants may be included to increase drug solubility by solubilization into micelles. Both the USP 24 (9) and the BP 2000 (8) indicate that the pH of dissolution-fluid should be within 0.05 of that specified in the relevant monograph.

The inclusion of alcoholic solvents, for example, isopropanol, has been advocated for insoluble drugs such as norethindrone and was used to provide a rank order of dissolution (30). The dissolution rates increased in hydro-alcoholic medium. Each component of a norethindrone–mestranol combination tablet gave its own dissolution rate in deaerated water but was not discriminated in the hydro-alcoholic medium. Therefore, for quality control purposes, all components of a multiple drug formulation should have their dissolution assessed. Problems are induced by the inclusion of cosolvents. Alcoholic solvents may retard dissolution rates by retarding disintegration as, for example, during the dissolution of chlorthalidone into 40% aqueous methanol (31).

Sink conditions may be accomplished by using dissolution media consisting of two phases to allow partition of the drug into the organic phase; the use of organic solvents such as hexane may provide sink conditions. Supramicellar surfactant concentrations may be used for drugs of low solubility (<0.01% w/v). Consequently, sodium dodecyl sulfate may be added to the media. However, the inclusion of surface agents into the dissolution media may make the media less discriminatory. The use of 0.4% sodium dodecyl sulfate was proposed as an alternative to 0.1 or 0.01 *M* HCl for the dissolution of rifampin (32) because the drug was more stable in surfactant solutions. After 1 and 2 h, in 0.01 *M* HCl, 13 and 29% of rifampicin decomposed, at 37°C. After 2 h, only 2% degraded in water.

Fig. 6 Schematic diagram of a flow-through dissolution cell.

IN VITRO–IN VIVO CONSIDERATIONS

Ideally, dissolution tests should provide data to distinguish good and bad formulations, changes in production processes that might influence bioavailability, batch to batch reproducibility, site and manufacturer variation, and information on the stability of the product. The test is used in the development of new dosage formulations, for quality control and to give indications for bioequivalence. In addition, one may consider the dissolution testing as a prognostic tool for in vivo performance (33).

Great care must be taken to produce good in vitro–in vivo correlations. This may be accomplished by creating a reproducible dissolution method that provides proper selection of medium, degree of agitation, etc. Ideally, this could be achieved if the gastrointestinal tract conditions were successfully reconstructed in the dissolution apparatus.

Using dissolution parameters, dissolution rate can be related to bioavailability for some drugs. For example, Kingsford et al. (34) showed a linear relationship between the percentage dissolved in 30 min and the bioavailability of frusemide relative to an oral solution when frusemide was examined using the rotating basket apparatus and buffer at pH 5.0. Therefore, in certain cases, it may be appropriate to apply dissolution testing data to evaluate biopharmaceutical implications of a product change rather than automatic bioequivalence study (35). The USP 24 (8) details the requirements for in vitro and in vivo evaluation of dosage forms, including immediate release and modified release dosage forms.

DISSOLUTION TESTING OF MODIFIED-RELEASE ARTICLES

The USP 24 (8) also gives tests (termed “drug-release” tests rather than dissolution tests) for modified release products, which includes extended-release (sustained or slow-release) products and delayed-release (enteric-coated) articles. The former are described as allowing at least a two-fold reduction in the dosing frequency as compared with that drug presented as a conventional dosage form. A delayed-release article is one that releases the drug at a time other than promptly after administration.

The USP 24 testing of both extended-release articles and delayed-release articles proceeds via three stages. For extended-release products three time points are generally

specified, expressed in terms of the labelled dosing interval (D in hours). The amounts dissolved (Q) at each time interval are expressed in terms of the labelled content; the limits embrace each value of Q , the amount dissolved at each specified dosage interval (8). Initially six units are tested. No unit should lie outside the stated range or be less than the stated amount at the final test time. Failure at this stage leads to examination of a further six units whose results are combined with the initial results. The average of the 12 units should not lie outside the stated range and should not be less than the stated amount at the final test time. Additionally none should be more than 10% outside each of the stated ranges and none more than 10% of the labelled content below the stated amount at the final test time. Failure to meet these standards requires the testing of a further 12 units, the data being combined with those from the previous 12 units. The average of the 24 units is within each of the stated ranges and not less than the stated amount at the final test time. No more than two of the 24 units should release more than 10% outside each of the stated ranges; no more than two of the 24 units should release more than 10% below the stated amount at the final test time; and none of the units should be more than 20% of the labelled content outside each of the stated ranges or more than 20% of the labelled content below the stated amount at the final test time.

DISSOLUTION TESTING FOR ENTERIC-COATED TABLETS AND CAPSULES

The USP 24 (8) describes two general methods for delayed-release (enteric coated) articles, each method utilizing a change in pH. In method A, an acid stage consisting of 750 mL of 0.1 M HCl is used. An aliquot is withdrawn after 2 h for assay. The pH is then raised by adding 250 mL of 0.2 M tribasic sodium phosphate and adjusted to pH 6.8 ± 0.05 and the dosage forms are operated for a further 45 min. Method B utilizes 1000 mL of 0.1 M HCl operated for the initial 2 h period and the fluid is completely replaced with 1000 mL pH 6.8 phosphate buffer and run for 45 min. Again, three levels of testing are used for the HCl stage (8).

In addition to the official tolerances for delayed-release products, commercial manufacturers will have their own in-house specifications. Standards for enteric-coated forms ensure the integrity of the coat, but consideration should be given to a pH change method for evaluating extended-release medications. This evaluation should ensure that

dose dumping does not occur at a specific pH, as might be a problem with delayed-release dosage forms based on, for example, hydroxypropyl methylcellulose phthalate.

DRUG RELEASE FROM SUSTAINED-RELEASE ARTICLES

There have been various testing schedules that have been developed to study the influence of pH changes, for example, from 0.1 *N* HCl to pH 7.5 (36) or a progressive rise from pH 1.5, 4.5, 6.9, 7.2–7.5 over 22 h (37). Such changes are designed to follow the pH changes during the passage of a dosage form through the gastrointestinal tract, but the residence time in the tract can be as little as 4–6 h up to in excess of 24 h depending on the food that the patient has ingested. An alternative approach is to develop topographic profiles of the matrix tablets to determine the dissolution profiles at a variety of pHs (38); an apparent three-dimensional profile of amount released versus time versus pH is produced. Such profiles may be used to determine over which pH range dosage forms release their drug at a faster rate than required, thus avoiding the problem of dose dumping at a particular narrow pH range.

In the development stage of new modified release dosage forms, it is vitally important to not only consider dissolution testing as a quality control tool but also as a prognostic tool to discriminate in vivo good and bad formulations. Therefore, one needs to understand the mechanism of drug release from the dosage form in order to utilise the dissolution testing effectively. For extended-release reservoir formulations, where the drug was dissolved and released by diffusion through a barrier coat, factors such as the influence of medium on solubility of the drug need to be established.

In the case of hydrophilic-matrix sustained-release formulations, drug release is via diffusion through and erosion of the hydrated viscous surface polymer. Therefore, factors that may provide additional strength or support to this surface polymer, must be minimised. For example, during the dissolution testing of a large swelling matrix, it may be supported by the basket wall, which combined with slow speed of rotation leads to unrealistically slow drug release. This is in contrast to in vivo where due to agitation of the GIT and also presence of food, the level of erosion is greater and thus faster drug release may occur. A discriminating dissolution testing would assist the formulator to achieve the desired in vivo drug release profiles, through the formulation variables.

Figure 7 illustrates how the type of apparatus and also speed of rotation influences the in vitro drug release profiles of a HPMC matrix formulation (39). In another study, using HPMC matrix formulations, the in vitro data were successfully correlated to in vivo data with an excellent correlation when apparatus 1 at 150 rpm was used (40).

Matrix-sustained release tablets may present additional problems since they tend to stick to the side walls of the vessel, giving a reduction in the partial exposure of surface area and the use of the paddle may destroy the discreteness of the dosage form. Moreover, media containing high concentrations of phosphates may result in the disintegration of sustained-released matrices based on hydroxypropyl methylcellulose.

Pellets, beads, and other particulate systems intended to provide prolonged release are probably best tested by column methods that facilitate changes in pH or dissolution fluids. With compendial apparatuses, problems arise; for instance, it is difficult to capture dispersed particles when the paddle method is used, and small particles may pass through the mesh of the basket in the basket method.

Recently a simple (41) model was proposed using mathematical indices to define a similarity factor f_2 , to compare dissolution profiles as in Equation (4):

$$f_2 = 50 \log\{[1 + 1n_t^{n-1}(R_t - T_t)^2]^{-0.5} \times 100\} \quad (4)$$

where R_t and T_t are percent dissolved at each time point for the reference product and the test product, respectively. Using the f_2 values, dissolution profiles are considered dissimilar if these values were less than 50 with average difference between any dissolution samples not being greater than 50%. The similarity factor and a similarity

Fig. 7 Dissolution profiles of diltiazem hydrochloride from a swelling matrix system in phosphate buffer pH 6.8 at 37°C, using the basket and paddle methods rotating at 50, 75, and 100 rpm.

testing have been recommended for dissolution profile comparison in the FDA Guidance for Industry (35, 42, 43).

SUPPOSITORIES AND OTHER SEMISOLIDS

Semisolids are intended for percutaneous (ointments, creams, gels, patches), vaginal (pessaries), ophthalmic (ointments, creams, gels), or rectal (ointments, creams, suppositories, gels) release. Some estimate of drug release is desirable to ensure that the drug is not entrapped by preferential partitioning into the oleaginous phase. Unlike tablets and capsules, there must be some constraint on the surface area of such preparations exposed to dissolution fluids to produce a quantitative estimate of release during dissolution studies.

Suppositories create problems because they soften, deform, disintegrate, and change from a solid to an oily state during the test. Glass beads will control the interfacial area during a dissolution test; consequently, the use of a continuous-flow bead-bed column-type apparatus was advocated for the dissolution of suppositories (44). Suppositories based on soluble carriers such as polyethylene glycol create fewer problems in the assessment of drug release since the carrier rapidly dissolves. However, oleaginous-based suppositories (e.g., containing cocoa butter) will melt slowly and spread, giving a constantly changing surface area. Consequently, membranes are frequently employed to entrap the suppository although they may themselves be the factor that limits drug transport. In addition, basket methods are unsuitable since the basket mesh will readily clog although polyurethane baskets of dimension similar to the USP basket have been used. To design a realistic apparatus for both types of suppository probably require two phases.

Transdermal patches have also been examined. The USP 24 (8) includes reference to transdermal drug delivery systems. The temperature of operation is specified as $32 \pm 0.5^\circ\text{C}$. Apparatuses include a modified paddle method, using a disc, 41.2 mm in diameter, to locate the patch at the bottom of the dissolution flask, a cylinder method whereby the patch is attached to the outside of a stainless steel cylinder of radius approximately 2.2 cm and rotated in the dissolution flask, or a reciprocating disc apparatus such that the disc may be reciprocated at 30 cycles/min over an amplitude of 2 cm in volumetrically calibrated solution containers.

ROBOTICS

Dissolution by manual methods is very labor-intensive and time-consuming. Therefore, the use of microprocessors is cost-justified, especially when some tests may take up to 24 h. Robotics speed up assay techniques; rapid insertion and withdrawal of a small sample probe, controlled robotically, produces minimum disturbance of the hydrodynamic conditions. The use of robotics increases the speed of assay, the throughput and the productivity of dissolution testing. However, the speed of assay may then be the rate-limiting step to productivity. Consequently, to speed up the assay process, short high-pressure liquid chromatography (HPLC) columns may be used to increase assay speed.

ASSAY METHODS

Whatever assay technique is chosen, it must be specific to the drug under assay. For single-drug entities, UV or HPLC assays are most suitable and most used; even ion-specific electrodes can be used to monitor drug release in the presence of a suitable anion or cation. However, with any trend to multiple dosage forms, more complicated assay techniques may be required, which makes HPLC useful since more than one drug can be analyzed in the same chromatogram. The use of UV photodiode array spectrophotometry has become popular with multidrug dosage forms.

DESIGN OF DRUGS: BASIC PRINCIPLES AND APPLICATIONS

Jacques H. Poupaert

Université Catholique de Louvain, Brussels, Belgium

INTRODUCTION

Drug design and discovery techniques have evolved considerably in recent years but they have progressed in two opposite directions. On the one hand, considerable intellectual and financial efforts have been made to implement a rational sequence of events that would ultimately result in the identification of the successful drug candidate. One of these scenarios is known as “structure-based drug design.” At the turn of the millennium, this can be considered as the ultimate stage of development of “rational drug design” (1–4). On the other hand, with the potentialities offered by automated chemical synthesis and robotized biochemistry, the temptation has been ever greater to produce increasingly huge numbers of molecules by combinatorial chemistry techniques and include them in batteries of high throughput screening (HTS). The process of finding novel, active compounds through combinatorial chemistry is akin to finding a needle in a haystack. While per se not irrational, this process can be viewed as using a Monte-Carlo algorithm and as such it can be easily anticipated that convergence in the selection of the successful drug candidate will be inevitably slow. The challenge of the next century will be to reconcile these two approaches to significantly accelerate both discovery and preclinical research. Building a fully integrated, high-throughput drug-discovery platform spanning lead generation through investigational new drugs (INDs) at present remains a critical step to be made in order to efficiently transform proprietary medicinally designed combinatorial libraries into wholly or substantially owned new chemical entities (NCEs).

STRUCTURE-BASED DRUG DESIGN

Historically, the pharmaceutical industry has relied on discovering drug leads by screening-sifting through vast inventories of either naturally occurring or manmade chemicals in search of previously undiscovered substances with the desired biological activity. Traditionally, optimization of a lead compound was achieved by random exploration of a chemical structure (often called lead

compound) through the synthesis of large numbers of chemical derivatives. Over the last decade, this approach has become increasingly unsatisfactory, since it is costly and inefficient, and while the rate of discovery of new therapeutic compounds and the marketing of new drugs has declined, the costs have continued to rise. Most importantly, there remain many important therapeutic needs for which screening-based research has failed to yield acceptably safe and effective drugs.

Almost all biologically active molecules work via an interaction with a “target” or “receptor” molecule that plays key roles in all biological processes. In the most common perception of this interaction, the drug molecule inserts itself into a functionally important cleft of the target protein, such as a key in a lock. The molecule then binds there and either induces or more commonly inhibits the protein’s normal function. This universal drug-target scheme suggests an interesting alternative approach to drug discovery. Indeed, if it were possible to identify in advance the appropriate protein target for a searched therapeutic need and if enough information were known about the structure of that target protein, it ought to be feasible to design the structure of an ideal drug to interact with it. This approach, called structure-based drug design (5–10), offers the promise of eliminating much of the inefficiency of the classical approaches of conventional drug discovery.

Scientists therefore developed an approach for drug discovery that exploits the 3-D structures of molecular targets (protein structure-based drug design; Fig. 1). At the heart of this strategy is protein X-ray crystallography, which enables one to determine the 3-D atomic structures of target proteins and the drugs that bind to them. This novel approach to drug design integrates genetic engineering techniques that allow the identification, purification, and modification of appropriate target proteins with innovations in protein X-ray crystallography (11–14). This approach also uses elaborated softwares that permit chemists to predict molecular structure in its dynamic and thermodynamic extensions. In contrast to the biotechnology industry, several pharmaceutical groups nowadays employ genetic engineering techniques to produce proteins not as products, but as drug targets. Genetic engineering techniques assist scientists in identifying molecular targets for particular therapeutic objectives, produce target

Fig. 1 The 3D vision of pharmacologically active molecules (here taxol) provides the medicinal chemist with a complex information from which a pharmacophore has to be deduced to generate analogs with more adequate pharmacokinetic and toxicological properties.

proteins in sufficient amounts to permit structural studies, and modify these proteins to probe the connections between a target protein's structure and its physiological or pathological functions. So far, the only method that has been successful in determining the precise 3-D atomic structure of large proteins is X-ray crystallography. An important limitation of the method is that X-ray crystallographic studies require a target protein in crystalline form. A powerful X-ray beam bombards a single protein crystal, which diffracts the X-ray beam and generates a definite diffraction pattern. A complex analytical process involving extensive mathematical computations then has to be performed on the X-ray diffraction data. The results of these calculations determine the target protein's exact 3-D structure. It is this information that provides the critical starting point for 3-D drug design. Alternatively, when the target protein cannot be obtained in crystalline form, 2-D nuclear magnetic resonance (2D NMR), or molecular modeling techniques, can provide useful information.

Medicinal chemists and crystallographers begin the process of drug design after determining the 3-D atomic architecture of the target protein and its functionally critical regions. Using a variety of specialized programs on interactive graphics workstations, drug designers generate concepts of drug molecules that complement the unique structure and electronic environment of the target protein. Medicinal chemists then synthesize the most promising candidate structures. As in conventional drug-discovery

strategies, biochemists measure the ability of this newly synthesized drug candidate to produce the intended effects on the target protein. Crystallographers then redetermine the structure of the protein target now in combination with the candidate drug molecule included within the active site of the macromolecule. They see the detailed structural interactions actually achieved by the candidate drug with its biological counterpart. Scientists relate the performance of such a compound measured by conventional biochemical or pharmacological techniques to its structural interactions with the target as revealed by X-ray crystallography. The design team then incorporates the results of this analysis into its next generation of compounds. In this scenario, drug-design methodology consists of iterative cycles of simulation, design, synthesis, structure and biological performance assessments, and redesign. The power of this methodology lies in the ability of the drug designers to see the primary event in drug action, i.e., the interaction of the drug with its target as it actually takes place, and guide the design and optimization of drugs by the intimate details of this interaction.

DRUG DESIGN AND CHEMICAL DIVERSITY

In the 1990s, the average cost for introducing a new drug entity to the marketplace was estimated at greater than

\$300 million dollars. Of this dollar figure, nearly one-third has been estimated to go to the discovery and optimization of a lead chemical structure. Each compound within a company's archives ultimately finds its origin in the labors of several chemists involved in the synthesis or the isolation and identification of natural products. The cost for the preparation of such compounds on a single-compound basis is very important. It has been estimated that the cost of preparing each novel molecule in the traditional pharmaceutical industry paradigm of individually synthesized molecules prepared in serial fashion is between \$5,000 and \$10,000. Clearly, an opportunity exists to reduce costs at this earliest stage of the drug-discovery process, i.e., the identification of a novel lead chemical structure (Fig. 2).

Lead structure compounds are currently identified through rational design and/or mass screening. In the past, routine mass screening has been rather successful in identifying new leads. With the recent introduction of high-throughput, automated screening technologies the evaluation of hundreds of thousands of individual test molecules per year against a large number of targets is now feasible. The source of large chemical libraries still remains a stringent limitation. Compound libraries commonly used in mass screening consist of either an historical collection of synthesized compounds owned by pharmaceutical companies or natural product collections. Each of these libraries has limitations. Historical collections contain a limited number of diverse structures (e.g., thousands of steroids, β -lactams, benzodiazepines, etc.) and, although quite useful, represent only a small fraction of the vast number of possibilities. Natural products are limited by the structural complexity of the leads identified and the (pharmaco) chemical difficulty of modifying them to useful pharmaceutical agents (e.g., taxol) endowed with the pharmacokinetic and toxicological properties required for the medical goal pursued.

During the past decade, a new source of compounds has arisen, i.e., those obtained through the rapid chemical or biological generation of compound libraries. This wealth of new compounds, coupled with the ability to rapidly

carry out their biological evaluation, represents an important shift in the traditional paradigm for generating and optimizing new lead structures not only for the pharmaceutical industry, but also for the agricultural, materials, and chemical industries. From its earliest days over a decade ago to the present, the field of chemical generation of molecular diversity has changed dramatically. Early attempts focused exclusively on the rapid generation of very large numbers of peptides, using solid- and solution-phase techniques. This was primarily due to the ready availability of the natural and unnatural aminoacids and the previous development of well-established coupling methodologies. The application of this approach can now rapidly generate hundreds of thousands to millions of small to medium size peptides for identifying novel leads or to help elucidate the chemical basis of known ligand-receptor interactions by preparing and evaluating a large number of peptide analogs. The new trend, however, is to focus on the generation of nonpeptide, low-molecular-weight compounds (commonly called peptidomimetic compounds). Combinatorial chemistry is one of the important new methodologies developed to reduce the time and costs associated with producing chemical diversity. Scientists use combinatorial chemistry techniques to create large populations of molecules (libraries) that can be screened efficiently en masse. By producing larger, more diverse compound libraries, companies hope to increase the probability that they will find novel compounds of significant therapeutic and commercial value. The field represents a convergence of chemistry and biology, made possible by fundamental advances in miniaturization, robotics, and biotechnology developments (15–17).

As with traditional drug design, combinatorial chemistry relies on the progress of organic synthesis methodologies. The difference, however, is the scope: Instead of synthesizing a single compound, combinatorial chemistry exploits automation and miniaturization to synthesize large libraries of compounds (Fig. 3). Scientists then need a straightforward way to find the active ingredients within these enormous populations. Thus, combinatorial organic synthesis (COS) is not random, but systematic and repetitive, using sets of chemical “building blocks” to form a diverse set of molecular entities. Scientists have developed several different COS strategies, each with the same basic philosophy; i.e., to find ways to determine active compounds within populations, either spatially, through chemical encoding, or by systematic, successive synthesis and biological evaluation (deconvolution).

Three common approaches to COS could be envisaged. During arrayed, spatially addressable synthesis, building

Fig. 2 It took more than 150 years to modify the complex morphine structure (left) to the simpler achiral morphinomimetic fentanyl, using classical drug-design methods.

Fig. 3 Example of modular construction of a multifunctional assembly, using solid-phase synthesis technology (A and B are variable alkyl or aryl groups; boc = benzyloxycarbonyl; Trt = trityl; Res = resin).

blocks are reacted systematically in individual reaction wells or positions to form separated “discrete molecules.” Active compounds are identified by their location on the grid. The second technique, known as encoded mixture synthesis, uses nucleotide, peptide, or other types of more inert chemical tags to identify each compound. During deconvolution, the third approach, a series of compound mixtures is synthesized in a combinatorial manner, each time fixing some specific structural feature. Each mixture is assayed as a mixture and the most active combination is pursued. Further rounds systematically fix other structural features until a manageable number of discrete structures can be synthesized and screened. Scientists working with peptides, for example, can use deconvolution to optimize, or locate, the most active peptide sequence from millions of possibilities.

As with traditional drug design, the ability to integrate different types of chemical, biological, and corporate information is crucial to combinatorial chemistry techniques. Combinatorial chemistry also generates an enormous amount of information, which present-day information systems still have a hard time managing. Combinatorial chemists also ask different questions in different ways, and their information systems need to adapt to find these answers quickly. For example, chemists planning a traditional synthesis typically conduct a retrosynthetic analysis to determine the best, and perhaps cheapest, way to obtain the target. In the same way, combinatorial chemists also look at retrosynthetic trees to build combinatorial libraries. Combinatorial chemists need rapid ways to access reaction information efficiently. One of the largest limitations in the construction of

combinatorial libraries is in obtaining the basic building blocks necessary to run each reaction. Chemical information systems that can quickly retrieve commercially available reagents are invaluable tools in reagent acquisition.

Once built, combinatorial libraries produce unprecedented amounts of useful information, provided a consistent quality of the pharmacological evaluation can be ensured throughout the whole process. Reaction histories for each compound must be archived. Robots and other laboratory instruments need permanent monitoring, and the data they acquire have to be archived for future reference. Scientists need to integrate screening results and biological data with structural information. As in single-molecule archival systems, the archival of combinatorial libraries and their corresponding data is essential to cost-effective research and development.

Combinatorial chemistry is a promising new field that stands to revolutionize the chemical industry, and demands completely new scientific information management solutions. Combinatorial chemists will be able to meet their goals if they can find ways to plan libraries quickly, produce libraries that better interrogate biological assays, and learn from past screening results. Libraries have to be designed to systematically order and explore the wide-ranging molecular themes represented in its building block collection. Within each thematic library, subclass chemical properties are to be varied systematically in order to aid medicinal chemists in fine-tuning lead profiles. Using software that can orchestrate the planning, building, screening, and interpretation of synthesized libraries, combinatorial chemistry programs will begin to realize

their promise of minimizing the time and cost associated with bringing new molecular entities to market. Proper management of combinatorial chemistry libraries requires software applications that understand the science behind combinatorial chemistry while managing the chemical and biological data generated by combinatorial chemistry programs (18–22).

HIGH-THROUGHPUT ORGANIC SYNTHESIS (HTOS) AND HIGH-THROUGHPUT SCREENING (HTS)

The pharmaceutical world has passed through a remarkable transition in the past decade in its efforts to identify novel compounds that interact with new molecular targets and to pave the way to new therapeutic agents and product lines. The impact was first apparent in the biological sphere as assays reached the micro level and automation permitted sample throughput in multiple screens, which was unimaginable a few years earlier. HTS was born and quickly adopted as an important, if not the only, source of the initial “hits” required for the generation of leads for commercial development (23–26). The importance and permanence of the HTS focus has been manifested within the organizational structure of most corporations. Such structures tend to be immovable and only bend when economic considerations surface at both the operational and future levels. HTS is such an event. Discovery has shifted from a closed chemist–biologist relationship into a complex multidisciplinary cell that has generated a new level of professionalism within the industry. Compound management alone constitutes new positions and occasionally departments in larger organizations. This function controls the fodder that HTS requires and essentially holds the key to the success of the discovery program.

The success of HTS in uncovering the unknown parameters of a new receptor site, however, relies on access to a vast collection of compounds that possesses a very broad range of chemical functional groups dispersed in 3-D space in diverse structural frameworks. This level of diversity is rarely found in a company’s archives. The development of most corporate collections has relied on acquisition from external sources. Initially, such access was primarily from universities and research institutes worldwide. The fragmentary nature of these resources spawned the creation of small industries, the compound brokers, who have served as “gofers” and data processors in the collection and marketing of such compounds. It is economically preferable for industrial groups to use these

brokers and avoid the need and expense of scouring the multitude of academic archives. A significant savings over that of in-house synthesis is realized; however, the number required to come close to reasonable diversity brings the required investment again to a substantial level. It has been estimated that the average cost of \$50 per sample places the overall expenditure for 100,000 compounds at ~\$5,000,000 plus handling, storage, and maintenance costs. While this value can be reduced with rigorous negotiation when large numbers are purchased, the better bargain is to purchase compounds preplated on microplates. The micro requirements of most HTS assays (<10 μ g) makes this latter approach especially attractive to small companies wherein acquisition and management costs of a large compound collection are prohibitive.

All of these external resources have relied heavily on the university as a primary source. An unfortunate consequence of these activities over the past decade has been a depletion of the academic resources that have accumulated over the past 50 years. Furthermore, the availability of useful quantities from current academic research has become less likely as modern chemical techniques and instrumentation permit studies with only a few milligrams. This is especially apparent in the natural product field, as the unique diversity inherent in that group has placed such acquisition at a premium. Market demands, nevertheless, persist and have led to the emergence of synthesis factories that prepare compounds specifically for the screening market, using conventional chemical techniques. Output has been greatly enhanced at some of these centers by adoption of modular approaches in synthesis. These sources have helped to fill the void in numbers, but have done little to enhance the level of structural diversity or the cost factor.

Chemists have addressed the sample resource question directly. The first approach was in the use of solid- and solution-phase techniques in the synthesis of large libraries of peptides, through combinatorial chemistry. Many discovery-based industries implemented in-house programs in combinatorial chemistry initially to explore the peptide as a supplement to their screening resources, but more recently in the use of the same technologies for the automation of general organic synthesis, as the limits and flexibility of the peptide backbone failed to satisfy the more general structural needs of discovery (Fig. 4). The success of this approach has led to the generation of a new chemical discipline, HTOS, the implementation of such programs as core technologies in many industries, and the emergence, once more, of new industries. Programs in academia also address this need, the tremendous potential it offers in the enhancement of structural diversity and the intellectual challenge of devising techniques for the

Fig. 4 Example of a three-step synthesis of a series of rather elaborated peptidomimetic compounds synthesized using straightforward reactions that can be easily automated in a fast parallel synthesis process. Methods: (a) acetic acid, polyphosphoric acid, 85°C; (b) RI, DMF, anhydrous potassium carbonate, room temperature; (c) Willgerdt-Kindler reaction (sulfur, secondary amine HNAB, DMF, 110°C).

tracking of the thousands of compounds generated as they proceed through a bioassay network. Several new industries have emerged within this specialized arena with chemical innovation and custom synthetic schemes that provide access to large chemical libraries which include features of specific interest to their client. The market and discovery impact has been dramatic.

Despite the excitement over the recent advances in HTOS development and the promises of prominent researchers in this area, HTOS cannot alone provide a diverse and sustained compound supply for screening. Today's technologies can achieve in parallel synthesis only the skeletal and functional complexity that is economically available through classical bench techniques. This aspect alone places full diversity outside the scope of HTOS because so far only a functional rather than a skeletal chemistry has been developed. Therefore, natural products still retain a commanding lead. While contributions to the enhancement of the structural diversity of a company's compound resources has, at best, been modest, the impact of HTOS on the economics of new drug development through rapid analog synthesis and the subsequent transposition of shorter development time into extended useful patent life has been dramatic. It is here that the strength of HTOS and its most important impact is felt.

The development of a lead into a product, in the traditional framework, is a stepwise process. The first stage is based on the assessment of synthetic possibilities within the limitations of organic synthesis and available starting materials, the extrapolation of preferred features defined

by precedence, any structure–activity relationships (SAR) information, and guides from computational analyses. This has not changed. The next step is the orderly planning of synthesis programs within the structural goals set for the target series, the development of timelines, which integrate synthesis with information feedback from primary and secondary bioassay, and further development of the synthetic targets. Analogs of an initial lead can be prepared singly at an average rate of 100 compounds per chemist per year depending on the complexity of the chemistry involved. In the traditional mode, the number of chemists employed on a project is defined by the management according to the significance of the discovery, the complexity of the syntheses, and the intended patent scope, the primary goal being a critical assessment of market potential and, if justified, the identification of preferred candidates for further development to a marketable product. The subsequent steps involve major capital investment in toxicology and clinical study. Thus, this selection stage is critical to corporate success and, in smaller companies, may mean eventual economic survival. A reasonable time for candidate selection in the traditional mode of drug discovery has been 1–2 years. The limiting factor has generally been the initial synthesis stage and the exploration of the numerous parameters associated with SAR development. With the application of HTOS design principles and robotics in organic synthesis, we see this time shortened dramatically. The 1- to 2-year period for candidate selection can be reduced by as much as 75%. This can constitute a significant extension in useful patent life by many months.

HTOS has clearly become a new chapter in chemical technology. It brings the excitement of further growth with the resolution of the obvious challenges of conducting chemical synthesis in arrays at semimicro and submicro levels. It also significantly impacts product development in the support industries as new goals are defined in liquid handling, automation, and data management. The corollary of this restructuring is the creation of new challenges for the organic chemist, a greater dependence on multidisciplinary interactions, and the internal structure of discovery departments. It has also created new scientific and engineering challenges and product opportunities that permeate support industries. Combinatorial chemistry has become a widely used tool both for the discovery and the optimization of lead structures. The demand for quality combinatorial libraries—characterized by diversity, novelty, purity, medicinal relevance, and facile synthesis—is clearly increasing. However, most of today's libraries provide only limited novelty, owing to the use of widely available commercial reagents and standard chemistries. In a near future, to achieve this goal of

chemical diversity it will be necessary to produce truly novel high-quality, value-added libraries which comprise a wide array of pharmacophore building blocks and scaffolds, featuring a broad range of molecular properties and chemical functionality.

DNA, FUNCTIONAL GENOMICS AND PHARMACO- AND TOXICOGENOMICS

In the past few years, we have witnessed a dramatic increase in the availability of genome-scale DNA sequence information from humans and several model organisms. New technologies incorporating this information are radically altering biological research. Toxicogenomics is a new scientific subdiscipline that combines the emerging technologies of genomics and bioinformatics to identify and characterize mechanisms of action of known and suspected toxicants. Currently, the premier toxico-genomic tools are the DNA microarray and the DNA chip, which are used for the simultaneous monitoring of expression levels of hundreds to thousands of genes (27–30).

An array is an orderly arrangement of samples. It provides a mean for matching known and unknown DNA samples based on base-pairing rules and automating the process of identifying the unknowns. An array experiment can make use of common assay systems such as microplates or standard blotting membranes, and can be created by hand or make use of robotics to deposit the sample. In general, arrays are described as macro-arrays or micro-arrays, the difference being the size of the sample spots. Macro-arrays contain sample spot sizes of about 300 μm or larger and can be easily imaged by existing gel and blot scanners. The sample spot sizes in micro-arrays are typically less than 200 μm in diameter and these arrays usually contains thousands of spots. Micro-arrays require specialized robotics and imaging equipment which generally are not commercially available as a complete system.

DNA micro-arrays, or DNA (gene) chips, are fabricated by high-speed robotics on glass or nylon substrates, for which probes with known identity are used to determine complementary binding, allowing massively parallel gene expression and gene discovery studies. An experiment with a single DNA chip can provide researchers with information on thousands of genes simultaneously—a dramatic increase in throughput. Why do some drugs work better in some patients than in others? And why may some drugs even be highly toxic to certain patients? Pharmacogenomics can be regarded as the hybridization of functional genomics and molecular pharmacology. The

goal of pharmacogenomics is to find correlations between therapeutic responses to drugs and the genetic profiles of patients. In the same way, toxicogenomics is the hybridization of functional genomics and molecular toxicology.

Pharmacogenomics uses genetic and genomic information to predict the response of individual patients and patient populations to drugs. Pharmacogenomics will have an impact on medicine by allowing the use of newly created genomic diagnostic tools to predict which drugs will have the greatest chance of success in treating individual patients safely and effectively. Eventually, drug prescriptions may be tailored or customized to the individual patient's genetic make-up, using this technology. Pharmacogenomics also has the potential to revolutionize the planning and design of clinical trials. By identifying which patients will respond to compounds being tested, as well as by eliminating those who may be at risk for adverse reactions, pharmacogenomics can improve the success rate of clinical development and reduce development time and cost.

The development of quantitative structure–toxicity relationships (an extended form of QSAR) to predict and to help understand the toxicity and metabolism of drugs now becomes an additional challenge for the efficient discovery of new drug candidates. Indeed, while HOTS and HTS techniques become more and more efficient to identify new lead structures and convey adequate information about the description of new pharmacophores, as such these techniques do not give direct access to compounds devoid of toxicity and endowed with the expected pharmacokinetic properties required for the therapeutic goal pursued. At this stage of the research, the professional skills and talents of experienced “traditional” medicinal chemists are again of paramount importance for the success of the whole process. A criticism that can be addressed to HOTS and HTS techniques so far developed is that, to increase potency and selectivity of the future drug candidate, relatively high molecular complexity is employed. These techniques of selection tend to unnecessarily increase molecular weight and lipophilicity and, as a result, the oral bioavailability (a major pharmacokinetic parameter) of such compounds will be inevitably very low or virtually zero. Consequently, after the discovery of initial leads, complementary programs of synthesis by traditional means are still necessary to produce grams of material necessary to assess the toxicological and pharmacokinetic properties. In this connection, while remaining somewhat empirical, the fundamental knowledge as well as the practice do exist. For this purpose, prodrugs have been intensively studied. However, this approach again tends to increase the

molecular complexity and, therefore, the molecular weight. It is, therefore, more and more envisaged to develop approaches with an integrated view of this enormous problem involving, at a very early stage, considerations of structure–toxicity and structure–metabolism relationships with the help of computerized expert systems.

The rapid evolution of the field with many techniques and disciplines involved poses the problem of the basic education and training of the personnel. While the relationship between academia and industry is frequently examined from the perspective of research and technical collaborations, it is also important to view it in terms of supply of human resources by academia to meet the demands of industry. At this level, the educational system based on the Ph.D. programs offered by universities has taken some delay with respect to the culture of the companies. A significant effort will have to be made to fill an undoubted gap in current professional education. There is also an increasing demand from the industry for basic research in organic chemistry to develop new reactions that can be employed in HOTS.

CONCLUSION

In front of the ever-increasing demand by the society and the authority for better drugs at lower cost, the pharmaceutical industry has developed sophisticated techniques of drug design, encompassing HOTS and HTS techniques to speed up the duration and the cost of drug discovery. While these techniques have not reached the level of superb maturity, they have considerably influenced the culture of the companies. However, per se these new methodologies do not directly deliver the new drug candidate, and, therefore, complementary programs of traditional medicinal chemistry are still necessary for the fine tune-up of the drug candidate. Consequently, drug design at present is made of a blend of modern technology and more classical science. The making of a blend has always been an art. It can be anticipated that in the future century drug design will evolve between these two trends, a blend of science and art in which the human being is central.

DENTAL PRODUCTS

Sebastian G. Ciancio

State University of New York at Buffalo, Buffalo, New York, U.S.A.

INTRODUCTION

A considerable number of products are now recommended for use in the oral cavity. Products for caries control are widely used and include fluorides in dentifrices and mouthwashes. Plaque control is achieved through the use of chemical agents such as chlorhexidine and quaternary ammonium compounds. Mechanical products for plaque control include dental floss, toothpastes, and mouthwashes. Products also exist to combat halitosis, act as topical anesthetics, desensitize sensitive teeth, act as tooth-bleaching agents, and assist in reducing xerostomia. More recently, products designed for the local delivery of antimicrobial agents to the oral cavity have also been made available. These, and other products, are reviewed in this article.

CARIES CONTROL USING FLUORIDES

Over 300 million people worldwide now consume optimally fluoridated water. The U.S. Public Health Service has established recommended levels for fluoride concentrations in water supplies in accordance with mean annual temperatures (1). The daily intake of fluoride not only comes from drinking water but also from food consumed or prepared with fluoridated water. Also, crops are frequently fertilized with phosphate fertilizers of high soluble-fluoride content, and food products including bone in animal feeds contain fluoride.

Naturally fluoridated foods and water have been ingested for decades with no serious side effects. In addition, public fluoridation has been widespread in this country for over 30 years without serious adverse effects. The incidence of mottled enamel, one of the earliest and most sensitive signs of fluoride toxicity, has not increased significantly in the past 15 years of water fluoridation. The safety and efficacy of fluoride has definitely been established, with no scientific evidence against fluoridation.

Mechanism of Action

The mechanism by which fluoride prevents caries is not clearly understood. It is known that the fluoride ion (F^-)

can replace the hydroxyl ion (OH^-) in hydroxyapatite, the major crystalline structure of enamel. The substituted crystal, called fluorapatite, is more resistant to acids, such as those produced by plaque bacteria, than the original hydroxyapatite.

As the tooth develops and enamel is formed, ingested fluoride is incorporated into the enamel. Therefore, because enamel develops its outer layer first, more fluoride can be expected to be deposited on the outer layers as compared to the inner layers. It is this surface enamel layer containing fluoride that imports, in part, caries resistance to a tooth (2). Topical fluorides also become incorporated into enamel and provide protection against acid. A number of studies have now shown that topical fluorides may be most beneficial in early enamel caries and that there is an increased uptake of fluoride in early lesions, with some tooth remineralization occurring. This finding has caused some investigators to label fluoride as a remineralizing agent as well as a caries inhibitor. The incorporation of fluoride into enamel can be represented as a chemical reaction:

Dental plaque also tends to concentrate fluoride. This could increase possible antienzymatic activity. Some caries protection from this may be expected. Additionally, studies have suggested that topical application of fluoride may also reduce smooth surface plaque, with a resulting beneficial effect on the periodontal tissues (3).

In areas where there is no fluoridation of the community water supply, fluoride may be added to school water. This is not a substitute for community water fluoridation because fluoride intake from birth is important.

In some areas where fluoride is absent from drinking water, the school water supply has been fluoridated as much as 4.5 times the level usually recommended for community water levels. These studies, conducted for 12 years in fluoride-deficient areas, revealed a 40% reduction in DMF surfaces. Essentially, no undesirable fluorosis resulted from this procedure. However, it should be noted that ingestion occurred only during part of each day and only on school days. This level (4.5 ppm) from birth (during major formation of permanent teeth) would cause undesirable fluorosis with continued intake (4).

Therapeutic Effects

Fluoridated water

The administration of fluoride in drinking water at concentrations of approximately 1 ppm significantly reduces dental caries. The anticaries benefits are similar to those due to natural fluoride in drinking water. Fluoridated drinking water produces the following: a 60% lower dental caries rate, a 75% decrease in the loss of 6-year molars, and a 90% reduction in the incidence of proximal caries of the four upper anterior teeth.

Evidence suggests that greater inhibition of caries occurs when teeth receive fluoride throughout the calcification period. Therefore, maximum benefit may be expected from the continued use of fluoridated drinking water.

Dietary supplements/tablets

Maximum benefits to both deciduous and permanent teeth may result from daily fluoride supplements from infancy until approximately 13 years of age, at which time all permanent teeth except the third molars should have erupted. Because cariostatic benefits may tend to diminish gradually after fluorides are discontinued, periodic applications of topical fluorides may then be necessary.

The use of dietary fluoride or topical applications of fluoride depends partly on the age of the child. Dietary supplements of fluoride are best for very young children, whereas topical fluoride applications are preferred for older children with permanent teeth. Younger children who are highly susceptible to caries may benefit from both measures.

The natural level of fluoride in drinking water where the child lives should be known before dietary fluoride is prescribed. At present, it is suggested that fluoride supplements be limited to where drinking water contains 60% or less of the optimal level of fluorides recommended for community water in the geographic area.

As a precaution, no large quantities of sodium fluoride should be stored in the home. It is recommended that no more than 264 mg of sodium fluoride be dispensed at any one time, which is enough for at least a 4-month period (5). Each package dispensed should also bear the statement: Caution—store out of the reach of children.

Although the optimal level of fluoride in drinking water is well documented, there is no established allowance for fluoride administered once a day. The standard allowance is 1 mg/day for a child over 3 years of age and one-half this amount for a child between the ages of 2 and 3. A more accurate method to use in calculating the daily fluoride needs of a child is to administer a dose based on the child's weight, for example, .025 mg/lb of body weight. However,

Table 1 Adjustment of prescribed fluoride relative to natural content of drinking water for children over 6 years of age

Water fluoride (ppm ^a)	Adjusted allowance sodium fluoride (mg/day)	Provides fluoride ion (mg/day)
0.0	2.2	1.0
0.2	1.8	0.8
0.4	1.3	0.5
0.6	0.0	0.0

^a1 ppm = 1 mg/L.

for all children over 6 months of age, the dose should not exceed 1 mg/day of fluoride ion regardless of weight. In order to avoid the possibility of unesthetic dental fluorosis, the prescribed dietary allowance should be reduced in proportion to the fluoride levels in the drinking water. Table 1 illustrates empirical adjustments for varying amounts of natural fluorides in communities where the recommended optimal level of fluoride is 1 ppm. These allowances are for children over 6 years of age. The allowances should be reduced for children 6 years of age and under, as shown in Table 2 (6, 7).

For children under 6 months of age, experts question the value of prescribing fluoride supplements.

Dental caries have been prevented when fluoride tablets were administered in a school-based program. After two or more years of fluoride ingestion, protection against dental caries ranged from 20–40% (8). In an extended trial of fluoride tablets reported in the literature, there was a 36% reduction in dental caries after 8 years (9).

The use of fluoride tablets can provide both a preeruptive (endogenous) effect and a posteruptive (topical) effect. Therefore, tablets should be chewed or dissolved in the mouth and the teeth rinsed with the resultant solution before swallowing.

One advantage of fluoride tablets compared to water fluoridation is that a specific dosage of fluoride is delivered.

Table 2 Adjustment of prescribed fluoride ion relative to natural content of drinking water for children under 6 yr of age

Patient's age	Content of water fluoride ^a		
	0–0.3 ppm	0.3–0.6 ppm	>0.6 ppm
0–6 mon	0.0	0.0	0.0
6 mon–3 yr	0.25	0.0	0.0
3–6 yr	0.50	0.25	0.0

^a2.2 mg prescribed sodium fluoride = 1 mg fluoride ion.

One disadvantage is that dietary supplements of fluoride taken once a day are rapidly cleared from the body.

Breast-feeding

Fluoride levels in human breast milk have been found to be less than 0.05 ppm. This concentration remains constant, regardless of drinking water and maternal plasma levels. Thus, breast-fed infants who receive no formula bottle feedings ingest considerably less fluoride than infants receiving formula mixed in 1 ppm fluoridated water. Fluoride supplementation for breast-fed infants should be considered.

The administration of fluoride supplements to expectant mothers in an effort to benefit the teeth of the offspring has been evaluated in several studies (10, 11). The evidence, however, is not sufficiently conclusive to warrant recommendation.

Vitamins

Vitamin preparations containing sodium fluoride are also available as drops, tablets, and chewable tablets. These forms of supplementation are useful in areas where the water supply contains less than 0.6 ppm, and they offer a way to provide fluoride to the child, if the parents are conscientious in dispensing the required amount daily and if the child does not object to taking oral medications. In recommending vitamins with fluoride, it is mandatory that one know the fluoride content of the child's water supply, as well as the fluoride content of the vitamin being recommended.

Topicals

Fluoride can be applied topically in various forms, offering the practitioner a number of options to choose for his or her patients.

Topical agents are of lesser value in a caries reduction program when they are used in fluoridated communities. However, when used in nonfluoridated areas, they are more effective (12, 13). In such areas, they often are the only form of fluoride therapy available.

The dosage forms of topical fluoride currently available include varnishes, dentifrices, solutions, gels, mouthwashes, and prophylaxis pastes. These various forms are outlined in Table 3.

Dentifrices

The earliest fluoride dentifrices contained sodium fluoride. However, the fluoride was biologically unavailable because the calcium in the dentifrice abrasive bound the fluoride and thus inactivated it.

Although a number of dentifrices containing fluoride are on the market, not all provide available fluoride because the abrasive systems that some dentifrices contain inactivate the fluoride. Therefore, the product may contain as much fluoride as any other dentifrice but it is not available. Also, if the product has a short shelf life, it will be ineffective if poor marketing gets it to the consumer too late.

For these reasons, only dentifrices approved by the Council on Scientific Affairs of the American Dental Association (ADA) should be recommended. These

Table 3 Various topical fluoride preparations

Preparation	Form	Formulation
Acidulated phosphate fluoride	Topical solution	1.23% in 1% phosphoric acid
	Topical gel, foam	1.23% in 1% phosphoric acid
	Mouthrinse	0.02–0.04%
	Prophylaxis paste	1.2%
Amine fluoride	Dentifrice	1.6%
	Mouthrinse	2.5%
	Topical solution	2%
Sodium fluoride	Mouthrinse	2.5%
	Foam	0.2%
	Varnish	5% (every 3–6 months)
	Dentifrice	0.76–0.8%
Sodium monofluorophosphate	Topical solution	8%
Stannous fluoride	Mouthrinse	0.1%
	Prophylaxis paste	8%
	Dentifrice	0.4%
	Gel	0.4%

Table 4 Representative dentifrice ingredients

Brand name	Fluoride	Abrasive	Sweetener
Aim	0.8% Sodium MFP	10% hydrated silica xerogel 19% hydrated silica	67% Sorbitol
Aim extra strength	1.2% Sodium MFP		
Aquafresh	0.76% Sodium MFP	12.6% Calcium carbonate 12% Silica	52.8%
Colgate®	0.76% Sodium MFP	48.76 Dicalcium phosphate	22% Glycerin
Crest®	0.24% Sodium fluoride	20% Hydrated silica	50% Sorbitol 18% Glycerin
Macleans	0.76% Sodium MFP	38% Calcium carbonate	29.55% Glycerin

products are listed in that association's publications and carry the ADA seal on their packaging.

Currently accepted dentifrices contain sodium monofluorophosphate, sodium fluoride, or, less frequently, stannous fluoride, all of which reduce caries by approximately 25% when used daily. In some clinical studies, stannous fluoride dentifrices stained teeth, particularly in pits and fissures (14). This stain is related to the tin in this compound, which adheres to plaque. The significance of this staining and its esthetic problems have resulted in a decreased usage in dentifrices. Stannous fluoride dentifrices are marketed in a plastic container because a reaction of stannous ions at an acid pH occurs when conventional soft metal tubes are used.

The composition of some popular toothpastes is important for a proper understanding of this topic. With the exception of extra strength products, the various dentifrices are formulated to provide 1000 ppm of fluoride. Comparative compositions of some fluoride dentifrices are shown in Table 4.

Since children ingest most of the fluoride toothpaste when they brush their teeth, only a pea-sized amount should be placed on the brush.

Stannous fluoride

Dentifrices containing stannous fluoride as an active ingredient are no longer widely marketed; however, these formulations were the first to be evaluated for caries-reducing properties. Effectiveness in caries reduction varied from 23 to 34% (15, 16). One stannous fluoride dentifrice containing a patented stabilized form of stannous fluoride is marketed with a claim of both caries and gingivitis reduction. However, this product is not ADA accepted.

Currently, there are no ADA-approved, over-the-counter dentifrices containing stannous fluoride. However, there are a number of ADA accepted stannous fluoride

prescription products approved for application by the dentist or by the patient.

Amine fluoride

Clinical data from several long-term studies in Europe have demonstrated the effectiveness of the use of a dentifrice containing organic amine fluorides (17, 18). The amine fluorides also have strong plaque-reducing properties. However, although the amine fluorides may be more effective for caries reduction than other forms of fluoride, the FDA has not allowed these products to be extensively tested in this country.

Sodium fluoride

Sodium fluoride as an ingredient in dentifrices has been the subject of a number of clinical investigations. Recent studies of sodium fluoride dentifrices formulated to ensure ready availability of fluoride ions have shown anticaries benefits similar to those obtained in clinical caries trials with dentifrices containing stannous fluoride and sodium monofluorophosphate.

Clinical caries trials conducted under well-controlled, daily supervised brushing conditions have reported reductions in dental caries of approximately 25–48% (19, 20).

Sodium monofluorophosphate

A number of clinical studies have been conducted with dentifrices containing 0.76% monofluorophosphate (MFP). The data from these controlled clinical studies of sodium MFP dentifrices have indicated reductions in dental caries ranging from approximately 17–42% (21–23). Two studies indicating effectiveness were conducted in fluoridated communities. In clinical studies comparing this form of fluoride with sodium fluoride, the findings for caries reduction have been similar. Unlike dentifrices containing sodium fluoride, dentifrices

containing MFP are compatible with a number of abrasive systems; this is one of the reasons why there are more ADA-accepted products in this category.

Solutions and Gels

In children, a reduction of 30–40% in dental caries is seen with the following: 2% sodium fluoride, 8% stannous fluoride, and acidulated phosphate-fluoride products. No one agent appears to be superior to any other when used as directed.

Solutions of 8% stannous fluoride have been used to reduce caries (24). As with the other agents, the teeth are polished, dried, and isolated, and a 4-min application follows. The disadvantages of this solution are that it must be freshly prepared, some tooth discoloration (as discussed under dentifrices) has occurred, and it has an unpleasant taste that is difficult to mask.

Topical concentrated fluoride solutions are useful in children with high caries activity because they may have both a caries-arresting property and one of caries prevention. The frequency of application varies with the caries activity of the child. For children with an average incidence of caries, it can be applied annually between the ages of 3 and 13.

When gels are used, they are placed into a tray that is placed against the teeth so that the gel flows around all surfaces. Best results have been reported with custom-fitted trays. It has been estimated that about one-third of the total fluoride placed in a tray is actually available for uptake by teeth. The remainder is simply a filler for the tray, some of which is swallowed (25).

The value of topical fluorides on adults has not been established. However, some studies have suggested that the acidulated phosphate fluoride types may offer some caries protection. Recent reports have suggested that polishing of teeth is not necessary prior to the topical application of fluorides (26, 27). These studies have stated that deplaquing of teeth with a toothbrush is adequate and offers the advantage of not removing surface fluoride from tooth structure. This concept may be valid, and future investigations in this area should be encouraged.

Fluoride mouthwashes

Substantial research has been performed on the caries-inhibiting effect of fluoride mouthrinse products. The effectiveness of these topically applied fluorides varies with patient compliance.

The daily use of fluoride rinses by young children should be carefully monitored, and it should be noted that

the ADA does not recommend the use of fluoride mouthrinse for children under 6 years of age.

Moreover, because these products, when brought into the home, present a potential danger, the ADA Council on Scientific Affairs has recommended that these rinses should not exceed 300 mg of sodium fluoride. Fluoride mouthrinse solutions for use in school or community programs, however, are available in larger volumes, based on the assumption that storing and dispensing of the products in public settings will be closely monitored. The potential dangers involved with unsupervised ingestion of these products should be made known to both parents and children.

Studies evaluating the effectiveness of mouthrinses containing sodium fluoride have shown the usefulness of these agents for children living in nonfluoridated areas. Most studies have been conducted using a mouthrinse containing approximately 0.05% sodium fluoride used daily or a 0.2% sodium fluoride used weekly (28, 29).

The Council on Scientific Affairs has accepted a number of fluoride mouthrinses. All products discussed below have ADA Council on Scientific Affairs acceptance.

Some mouthrinses are marketed as a concentrate for dilution to recommended levels. If concentrates are used, special care should be exercised to keep them out of the reach of children. The products are not packaged in glass containers, because the pH becomes more alkaline in glass. Plastic is the container of choice. Examples of prescription and nonprescription products follow.

ACT

This product is an aqueous solution of 0.05% sodium fluoride. It also contains 8% glycerin, 7% alcohol, a detergent, a preservative, saccharin, coloring, and flavoring agents. It is intended to be used on a daily basis and is available without prescription.

Fluorigard

This product is available as a rinse containing an aqueous solution of a 0.05% sodium fluoride, 15% glycerin, 5% alcohol, a detergent, a preservative, saccharin, coloring, and flavoring agents. It is intended to be used on a daily basis and is available without a prescription.

Fluorinse

This product contains 0.2% sodium fluoride as the active ingredient. It also contains a detergent, a preservative, flavoring, and color agents. It is intended to be used on a daily basis and is available without a prescription.

Phos-Flur oral rinse supplement

This product is an aqueous solution containing 0.044% sodium fluoride, 0.055% phosphoric acid, 1.35% sodium biphosphate, and flavoring and coloring agents. It is intended to be used once daily and is available by prescription.

Desensitizing Agents

A number of studies have reported that topical fluoride application may reduce dental hypersensitivity (30–32). These results have been found when concentrated dosage forms have been applied ranging from 8% stannous fluoride gels to 33.3% sodium fluoride paste. It has been shown that commercial dentifrices containing stannous fluoride may also decrease dental hypersensitivity. Also, a combination of stannous fluoride and potassium nitrate is marketed by one manufacturer to reduce sensitivity. Varnishes containing sodium fluoride have also been shown to reduce dental hypersensitivity.

CHEMICAL AGENTS FOR PLAQUE CONTROL

A number of chemical agents have been evaluated over the years in terms of their antimicrobial effects in the oral cavity and the importance of these effects on oral health.

In 1986, the establishment by the ADA of guidelines for acceptance of these products has served to stimulate properly designed clinical studies for evaluating potential therapeutic agents. Products that have earned the ADA's seal of acceptance are Peridex, Listerine[®], some generic copies of Listerine, and Colgate Total[®].

In this section, data on various available agents are presented according to chemical agent category. When the term *substantivity* is used, it refers to the ability of an agent to be retained in the area cavity and to be released over an extended time period with a continued antimicrobial effect.

Chlorhexidine

Of the products included in this report, chlorhexidine appears to be the most effective agent. Long-term studies in over 700 subjects showed reductions in plaque averaging 55% and in gingivitis 45% (33–35).

The mechanism of action of chlorhexidine is related to a reduction in pellicle formation, alteration of bacterial absorption and/or attachment to teeth, and an alteration of the bacterial cell wall so that lysis occurs. Chemically, it is classified as chlorhexidine digluconate and the U.S.

Adopted Name (USAN) designation is chlorhexidine gluconate. It has high substantivity. Adverse effects reported included staining of teeth, reversible desquamation in young children, alteration of taste, and an increase in supragingival calcified deposits. Long-term and microbiologic studies do not demonstrate the development of resistant strains. It is sold in the United States in a 0.12% concentration as a prescription mouthrinse (Peridex, PerioGard, and generically), which contain 11.6% alcohol with a pH of 5.5 and is approved by the ADA for control of plaque and gingivitis. Recommended usage is twice daily.

Fluorides

Fluorides are purported to have some antiplaque properties. The most widely used topical fluorides are stannous fluoride, acidulated phosphate fluoride, and sodium fluoride. Of the fluorides, short-term studies of stannous fluoride have been promising. However, long-term published studies showed lower plaque scores, but the differences were not significant (36, 37). No effect on gingival health was noted with the exception of one study.

With stannous fluoride, the mechanism of action appears to be related to an alteration of bacterial aggregation and metabolism. In summarizing the properties of this agent, it can be stated that it has moderate substantivity, that the antibacterial activity may be related to the tin ion, and that a 0.4% concentration may be the most effective. Stannous fluoride is the most toxic of the products considered and has the shortest shelf life. Adverse effects have been taste and black stain lines on teeth. Usage of once or twice daily favors compliance. Stannous fluoride is most often available as an aqueous gel.

Stannous fluoride products are accepted by the ADA for their ability to deliver fluoride but have not been approved for their plaque-reducing properties. Examples of accepted products are Activux Basic Control, Gel-Kam, Gel-Tin, Perfect Choice, Pro-Dentx, Schein Home Care, and Super-Dent.

Oxygenating Agents

In evaluating the efficacy of oxygenating agents, one must evaluate the endpoints selected for efficacy and their measurement. Oxygenating agents have anti-inflammatory properties. Therefore, less bleeding on probing, a major sign of inflammation, would be expected following their use, but the bacteria producing the disease process would not necessarily have been reduced. Peroxides are found in dentifrices in combinations with sodium bicarbonate in

concentrations of 1.5% or less. Also, they are found in bleaching agents discussed later in this chapter. As long-term studies of the effect of oxygenating agents are unavailable and short-term studies offer contradictory findings, questions of safety have been raised with regard to chronic use (38, 39).

Phenolic Compounds

Listerine

Short-term studies of phenolic compounds have shown plaque and gingivitis reductions averaging 35%, and long-term studies have shown plaque reduction averaging 35% and gingivitis reduction averaging 30% (40–42).

The only product in this category that has been adequately studied is Listerine. Listerine is a mixture of essential oils—thymol, menthol, a eucalyptol, and methylsalicylate. The mechanism of action appears to be related to alteration of the bacterial cell wall. This product is uncharged and has a low substantivity. Adverse effects reported have been a burning sensation and bitter taste. It is available in a 21.6–26.9% alcohol vehicle with a pH of 4.2. Recommended usage is twice daily, and the ADA accepts the product and some of its generic copies for the control of plaque and gingivitis.

Plax

Only short-term, clinical studies with small numbers of patients have been published. These pilot studies suggested some reduction in plaque when this product was used as a prebrushing rinse (43). Effects on gingivitis have not been reported. Additional long-term studies have questioned the efficacy of this product to reduce plaque and gingivitis.

The active ingredient is stated to be sodium benzoate. However, the product also has about 30% of some of the ingredients (oils) found in Listerine. It contains 7.5% alcohol. Usage is as a prebrushing rinse. It is not ADA accepted.

Quaternary Ammonium Compounds

Quaternary ammonium compounds have been evaluated in a number of short-term studies relative to their effect on plaque and gingivitis. In these studies, an average plaque reduction of 35% has been reported, with mixed effects on gingival health (44, 45). A 6-month study has been reported showing a 14% reduction in plaque and a 24% reduction in gingivitis (46). Cepacol®, Scope®, and Advanced Care Viadent™ are well-known representatives of this group, each with concentrations of approximately

0.05% cetylpyridium chloride. In addition, Scope contains 0.005% domiphen bromide. The mechanism of action is related to increased bacterial cell wall permeability, which favors lysis, decreased cell metabolism, and a decreased ability for bacteria to attach to tooth surfaces. These agents are categorized as being cationic, which favors their attraction to anionic surfaces of teeth and plaque. They are surface-active agents that alter surface tension and have some substantivity.

Adverse effects have been some tooth staining and a burning sensation in the oral cavity. These agents are available in a 14–18% alcoholic vehicle with a pH range of 5.5–6.5. Recommended usage is twice daily, and they are not ADA accepted.

Sanguinarine

Short-term studies of sanguinarine have shown some plaque and gingivitis reduction (47, 48). In the long-term studies of the product in a dentifrice form, no significant reduction in plaque or gingivitis occurred, with the exception of one study in which the product was used as a dentifrice and as a mouthrinse (49, 50).

The proposed mechanism of action is by alteration of bacterial cell surfaces so that aggregation and attachment is reduced.

Sanguinarine (benzophenathradine) is derived from the bloodroot plant (*Sanguinaria canadensis*). The extract concentration in the product is 0.03%, which equals 0.10% sanguinarine. It also contains 0.2% zinc chloride. The product may be cationic, and the degree of substantivity is unclear. Adverse effects have been a burning sensation and a question of epithelial cell dysplasia. It is available as Viadent toothpaste and Viadent mouthrinse. The mouthrinse pH is 4.5, the dentifrice pH is 4.8, and the alcohol content of the rinse is 11.5%. It is not ADA accepted.

Triclosan

Triclosan (2,4,4'-Trichloro-2'-hydroxydiphenyl ether) is a new antiplaque/antigingivitis agent available in dentifrices. The addition of a copolymer, vinylmethyl-ether maleic acid (Gantrez), has been shown to improve the effectiveness of triclosan by enhancing its retention (substantivity) by hard and soft surfaces. This formula (Colgate Total) has been approved by the FDA for sale in the United States, and is ADA accepted. Claims allowed are for the reduction of plaque, gingivitis, calculus, and caries. Studies as early as 1973 showed that this chemical agent had a broad spectrum, antimicrobial effect against a wide range of gram-positive and gram-negative bacteria found in the mouth. The minimal concentration of triclosan for oral pathogens is 0.3 mg/ml. Triclosan's

antibacterial activity is not affected by anionic agents, such as lauryl sulfate, which are essential to dentifrice and mouthwash formulations—a fact that broadens its range of use. In doses lower than 0.5%, taste perception is minimally affected; however, at concentrations of greater than 0.5%, undesirable effects on taste occur.

Zinc citrate

This agent is found in some tartar control dentifrices and also has some plaque- and gingivitis-reducing properties as found in Mentadent® and Advanced Care Viadent®. ADA does not accept dentifrices with this ingredient for reducing plaque and gingivitis

MECHANICAL PRODUCTS FOR PLAQUE CONTROL

Good control of plaque is accomplished by mechanical procedures, which include brushing, flossing, and professional prophylaxis. A professional cleaning is recommended at least twice a year to remove plaque and tartar (calculus), both supragingivally and subgingivally.

Brushing

A recent survey of brushing habits in the United States showed that only 60% of the public follow a strict brushing regimen. Clearly, motivation and education are needed in this area.

For the average adult, a soft brush with rounded bristles is most efficient in removing plaque from supragingival tooth surfaces (with the exception of the surfaces between the teeth). Most bristles are made of nylon, and the bristle ends are rounded. Subgingival plaque can be removed only to a depth of a few millimeters. For patients with a highly developed gagging reflex, a child's toothbrush is recommended. In addition, these patients sometimes find that placing a small amount of salt on the tongue is helpful in checking the desire to gag.

Studies of toothbrushing methods indicate that thoroughness is more important than technique. In the United States, the most widely used technique is one in which the bristles are directed into the gingival crevice at a 45° angle, and a gentle, jab-jiggle action is used. The motion is elliptical, rather than a back-and-forth scrubbing. Power toothbrushes are of special value for people who have motor coordination problems or difficulty in properly removing plaque by manual brushing. For children, the novelty effect of the powered brush is sometimes of motivational value. Also, a number of

studies have shown advantages of 10–15% better plaque removal than manual brushing.

Flossing

Surveys find that only 25% of the population questioned use dental floss regularly. Flossing is essential for removal of plaque from the surfaces between teeth and under the gumline, where the toothbrush does not reach. Because plaque has a propensity to build up in these areas, some dentists feel that flossing is actually more important than brushing.

Patients who do not have the manual dexterity to use dental floss can use the various types of dental floss holders or powered interdental cleaners (e.g., Braun InterClean and WaterPik Interdental Cleaner). Dental floss is available in waxed, lightly waxed, and unwaxed varieties. Most dentists feel that lightly waxed and unwaxed types are the most efficient in plaque removal. If the floss shreds or splits during use, this may be a sign of decay between the teeth or a defective filling margin. However, new flosses have been introduced that do not shred and are easier to use. The first of these new flosses was Glide Floss, followed by similar products from Colgate and Oral B®.

Disclosing Agents

Disclosing agents are dyes similar to those in food colorings that, when introduced into the oral cavity, color the supragingival plaque and make it easily visible. Various dyes are available in both liquid and tablet form. They are used in the dental office and at home both to increase the patient's awareness of plaque and to demonstrate where self-care has been ineffective in removing plaque.

Toothpastes

The majority of toothpastes advertised as specially formulated to control plaque contain (in addition to fluoride) a foaming agent and a mild abrasive, both of which facilitate plaque removal. However, the only toothpaste accepted by the ADA as possessing an active ingredient with proven ability to prevent or control plaque formation and reduce gingivitis is Colgate Total, with Triclosan as the active ingredient. Toothpastes claiming to be effective against plaque are simply more effective than brushing without any toothpaste because the use of toothpaste motivates people to brush longer and more thoroughly. In fact, it is mainly the mechanical action of brushing that removes plaque.

Toothpastes are effective as vehicles to deliver fluoride and Triclosan to the tooth surface, and although fluoride may have some effect against plaque bacteria and their enzymes, its major effect is to make the tooth surface more resistant to destruction by plaque bacteria. With the exception of Colgate Total, other toothpastes are accepted by the ADA for their fluoride content and effectiveness against tooth decay but not for their plaque- and gingivitis-reducing properties.

Other Oral Hygiene Aids

A number of devices aid in the removal of plaque from surfaces between teeth, around bridgework, and in other areas that are difficult to reach. The limitation of many of these devices is that they are effective for control of supragingival plaque but, at best, can remove subgingival plaque only to a depth of few millimeters. Therefore, they are of minimal value against subgingival plaque located deeper within the gingival crevice, as is the case in periodontal disease.

Various oral irrigators on the market remove some loosely attached plaque and particles of debris present around teeth and dental appliances, including braces (51). Because they are not effective in removing all attached plaque, they are not substitutes for brushing and flossing; rather, they should be used as adjuncts to these procedures (52). In addition, oral irrigators are limited in their ability to reach subgingival plaque. However, the introduction of subgingival applicator tips allows solutions to be delivered 6–7 mm apically.

Some studies have suggested that irrigators may alter plaque composition by eluting bacterial endotoxins (53). Patients with severely inflamed gum tissues should be cautioned to use irrigators at low pressures to guard against tissue laceration (if the tissue is severely inflamed), which may aggravate the existing problem.

Tartar (Calculus)-Reducing Products

A number of products, both dentifrices and mouthrinses, are available for reduction of supragingival calculus (tartar) in dental patients (54, 55). Calculus reduction has been shown with dentifrices containing pyrophosphates, zinc salts, triclosan, and papain.

The incidence of calculus formation ranges from 45 to 66%, with some variation between males and females and different age groups. Although supragingival calculus is not a major etiologic agent for gingivitis or periodontitis, its surface porosity provides an environment for plaque

formation. In addition, it serves as a plaque-delivery system by holding plaque against gingival tissues. Although plaque formation has been well correlated with gingivitis and periodontitis, a similar correlation for calculus has not been reported. For this reason, the ADA does not offer an acceptance program for products that reduce calculus formation because this is considered to be a cosmetic issue, rather than an issue of disease.

The mechanism of action of the calculus-reducing chemicals is related to the latter's ability to inhibit crystal growth and interrupt the transformation of calcium phosphate (found in foods and saliva) into dental calculus. This effect may occur as follows:

1. The agents complex on the tooth surface to block receptor sites for calcium phosphate that precipitates from saliva and chemically absorbs to initiate calculus formation.
2. This same receptor site blockage also occurs in the calculus matrix as it begins to form.
3. The pyrophosphate complexes combine with free calcium in saliva to inhibit the attachment at the tooth surface (probably a secondary mechanism).

Because these products offset mineralization, there has been concern over demineralization of teeth. All manufacturers have addressed this issue and have reported that this has not been a problem, probably because of the positive effect of fluoride on remineralization of dentin and enamel.

Some patients cannot use tartar control toothpastes containing pyrophosphates because they develop tooth sensitivity and sloughing of tissue (56). These adverse effects have not been reported with nonpyrophosphate-containing tartar control products such as those made by Den-Mat Corporation (Rembrandt[®] Toothpaste).

Crest tartar control dentifrice

This dentifrice contains 3.4% tetrasodium pyrophosphate and 1.37% disodium dihydrogen pyrophosphate to reduce calculus. Also, 0.243% sodium fluoride is included for caries reduction and prevention. It was the first calculus-reducing dentifrice introduced into the United States. On the basis of various clinical studies, a reduction of 30–40% can be expected. It has also been shown to significantly reduce the tooth staining seen in some patients who use chlorhexidine.

Crest tartar control mouthrinse

This mouthrinse provides 1.6% ionic pyrophosphate from disodium and tetrasodium pyrophosphate to act against calculus formation and 0.05% sodium fluoride as a

caries-reducing agent. Data on the extent of calculus and caries reduction were not available when this article was written because the product was in test market.

Colgate tartar control dentifrice

This product contains 5% tetrasodium pyrophosphate and a polymeric fatty acid with the company-patented name of Gantrez as the calculus-reducing agents. Also, 0.243% sodium fluoride is included for caries reduction and prevention. On the basis of various clinical studies, a calculus reduction of 35–50% can be expected. It is equal to Crest in terms of calculus reduction, with some clinical studies even suggesting a superiority to Crest.

Colgate tartar control mouthrinse

This mouthrinse contains tetrasodium pyrophosphate and tetrapotassium pyrophosphate, which provide 1% ionic pyrophosphate. It also contains 0.02% fluoride. Calculus reduction has been reported to be 35–40% with twice-a-day rinsing, with no claim made for caries reduction.

Listerine tartar control mouthrinse

This mouthrinse contains 0.09% zinc chloride to reduce calculus and also contains the same ingredients as Listerine mouthrinse.

Rembrandt mouth-refreshing rinse

This product has been shown to reduce tartar due to a formulation of surface-active agents and citroxain, a form of papain.

Targon[®]

This mouthrinse reduces staining due to a formulation of surface-active agents. With the introduction of these products, the practitioner is offered a variety of dosage forms and flavors. If one decides to recommend a calculus-reducing agent, the product selection should be based on the product the patient likes to use best and one that will not diminish his awareness of the importance of plaque control. For example, if he is not already using a mouthrinse, would its introduction de-emphasize the mechanical methods of brushing and flossing as a means of plaque and/or calculus reduction?

HALITOSIS

Local factors, systemic factors, or a combination of both can cause halitosis. It is estimated that 80% of all mouth odors are caused by local factors within the oral cavity,

and these odors are most often associated with caries, gingivitis, and periodontitis. Oral malodors occur because of the action of various microorganisms on proteinaceous substances, such as, exfoliated oral epithelium, salivary proteins, food debris, and blood (57, 58).

Studies have shown that saliva from individuals who are free of dental disease produces malodor less rapidly than saliva from patients with dental disease. It has also been observed that after prolonged periods of decreased salivary flow and abstinence from food and liquid malodors tend to be most severe.

Various oral bacteria produce products that are degraded to a number of compounds, foremost of which are sulfides and mucoproteins (59). These compounds have been most often associated with oral malodor. Specifically, it appears that oral malodor usually results from the bacterial-mediated degradative processes of methyl mercaptan and hydrogen sulfide in oral air. Ammonia is also produced but does not appear to contribute significantly to halitosis. It has even been suggested that ammonia production may improve the odor of mouth air.

Control of halitosis is directed at its etiology. If systemic factors are the problem, a medical consultation is indicated. If local factors are responsible, efforts should be directed toward their elimination. However, for many patients, systemic or local factors cannot be identified. Tongue scraping has been shown to reduce malodor in some patients.

Mouthwashes and dentifrices can serve an esthetic function by reducing halitosis. They can accomplish this by masking malodors, acting as antimicrobial agents, or both. There are no ADA-accepted products to reduce halitosis at this time.

TOPICAL ANESTHETICS

Topical anesthetic agents are selected for their ability to diffuse into the oral mucosa. Because many anesthetics used effectively for nerve block or infiltration do not adequately cross the mucosa, they cannot be used for topical anesthesia.

The concentration of anesthetic used for surface application is 2–5%. The rate of onset of topical anesthesia ranges from 2 to 5 min, is of relatively short duration, and has minimal effects deep to the area of application. One exception is a mucosal patch containing 10.4 mg of Lidocaine that gives anesthesia deep into the gingiva after a 5-min application period. Systemic absorption of topical anesthetics applied to the oral

mucosa is rapid, and blood levels may approach those seen following injection (60).

Several drugs used as topical anesthetics are not readily soluble in water but are soluble in organic solvents. They are, thus, prepared in alcohol, propylene glycol, polyethylene glycol, volatile oils, and other vehicles suitable for surface application. Their slower absorption rates make them safer for topical use on abraded or lacerated tissue. They produce anesthesia for short periods.

Topical anesthetics are useful to temporarily relieve the pain of ulcers, wounds, and other injured areas. The topical use of anesthetic agents before injection may produce superficial anesthesia. They are also of value in taking impressions or intraoral radiographs in patients with an excessive gag reflex.

Patients who are allergic to parenterally administered local anesthetics will also be allergic to topical application of these agents. In addition, as the agents may be absorbed into the systemic circulation, careless application of excessive amounts can result in signs of systemic toxicity. Symptoms of toxicity should be treated, as they would be for injectable agents. One can minimize the absorption of these agents by limiting the concentration of the drug, the area of application, and the total amount applied. In general, for topical anesthesia, one should use no more than one-fourth to one-half the maximum recommended dosage for injection of the agent.

Some topical anesthetic preparations are marketed in spray containers. These containers make it difficult to control the amount of material expelled and to confirm the agent was applied to the desired site. If these agents are applied to the posterior part of the mouth, a patient may inhale enough of the aerosol spray to provoke a toxic reaction (61). Use of topical anesthetics on the posterior pharynx may alter the swallowing reflex.

Benzodent

This ester-type anesthetic is poorly absorbed. Because it contains benzocaine, which has a low water solubility, it is prepared in a base containing petrolatum and sodium carboxymethylcellulose. Eugenol is included for its antiseptic and anodyne properties. Hydroxyquinoline sulfate is a preservative. This ointment can be directly applied to abraded or ulcerated lesions with minimal systemic effects. It is sometimes used to temporarily relieve denture sores and painful lesions.

Hurricane

This ester-type anesthetic also contains benzocaine and is prepared in a polyethylene glycol base with flavoring

agents added. It is available as a liquid, gel, or spray. The propellant for the spray is A 70.

Butyn

This ester-type anesthetic contains butacaine, with benzyl alcohol as a preservative. It is available as an ointment. The maximum dose is 5 ml of a 4% solution or 200 mg.

Cetacaine

This ester-type anesthetic is a combination of tetracaine HCl (2%), butyl aminobenzoate (2%), and benzocaine (14%). Benzalkonium chloride and cetyl dimethylammonium bromide are included as surface-active agents to facilitate the passage of benzocaine into the mucosal tissues.

Tetracaine is rapidly absorbed through biologic membranes and requires no facilitating agents. Because of its high toxicity and absorption, agents containing tetracaine should be used with caution and should not be placed under dentures. Spraying this agent is dangerous because the patient may inhale the aerosol. The maximum amount to be applied is 20 mg or 1 ml of a 2% solution. Cetacaine is available as a liquid, ointment, spray, or gel.

Xylocaine

This amide-type anesthetic contains a lidocaine base in a monoaqueous vehicle. It is available as a 2% viscous product containing lidocaine 2%, sodium carboxymethylcellulose, sodium saccharin, methylparaben, propylparaben, flavors, and purified water. It is also available as a liquid containing 4% methylparaben, sodium hydroxide, and flavoring agents. Another dosage form is a 5% ointment containing lidocaine 5%, polyethylene glycol, propylene glycol, and flavoring. The maximum dose is 300 ml of a 5% liquid form or 15 ml of the 2% viscous preparation.

DENTIFRICES AND SENSITIVE TEETH

Sometimes a patient will complain of teeth that are hypersensitive to heat and cold. These teeth usually have exposed root surfaces, sometimes with a loss of cementum. Most teeth, when in an ideal position in the mouth, have only the enamel surface exposed to the oral cavity. On occasion, such teeth may even respond with pain to extreme heat or cold.

However, in true dentinal hypersensitivity, the response to thermal and tactile changes is more pronounced, sometimes eliciting severe pain. Root surface exposure that allows contact with stimuli may occur because of gingival recession or following periodontal therapy.

Several theories have been advanced to explain the mechanism of dentinal hypersensitivity (62): innervation of the dentinal tubules, permitting transmission of impulses to the pulp, or the presence of lymph fluid in the dentinal tubules. In the latter case, exposure of dentin results in increased colloidal pressure on the tubules (thereby increasing pressure on the odontoblastic cells). Also proposed is a hydrodynamic mechanism involving the movements of tubular fluid in either direction, which elicits pain in the nerves of the pulp. Although no one theory has been proved, occlusion of the dentinal tubules by various methods brings relief. Various dentifrices are recommended for the treatment of sensitivity, with some success.

The greatest success occurs with dentifrices containing 5% potassium nitrate (e.g., Sensodyne[®], Rembrandt, Crest, AquaFresh[®], and Protect[®]), and some fluoride-containing dentifrices. Recently, a dentifrice containing potassium nitrate and stannous fluoride has been introduced to treat this problem (Colgate).

The primary mechanisms postulated for these dentifrices are that they occlude dentinal tubules, preventing stimuli from the oral cavity from irritating the dental nerve via these tubules. Also, those containing potassium may depolarize nerve fibers resulting in decreased impulse conduction and an associated decrease in pain.

For maximum effect, a patient must use only one of these dentifrices for at least a month. If no benefit occurs after a month, a different dentifrice should be recommended or other methods employed.

Topical varnishes containing sodium fluoride have also been shown to reduce dentinal hypersensitivity (e.g., Duraphat and Fluor-Protect) as well as reduce root surface caries.

BLEACHING AGENTS

Tooth-bleaching agents can be classified as to whether they are used for external or internal bleaching and whether the procedure is performed in the office by a dentist or at home by a patient. For tooth bleaching, hydrogen peroxide (H_2O_2) is used alone at levels of 30% or at 10–22% levels in a stable gel of carbamide peroxide (urea peroxide) that breaks down to form hydrogen peroxide (3.35% H_2O_2 from 10% carbamide peroxide),

urea, ammonia, and carbon dioxide. The FDA has not approved peroxide solutions for use as a home bleach, however.

Internal Bleaching

Internal bleaching produces reliable results when used to eliminate intrinsic stains in dentin caused by blood breakdown products or endodontics or for stains in receded pulp chambers. Internal bleaching is always an in-office procedure.

External Bleaching

External bleaching is indicated for teeth that are disclosed from aging, fluorosis, or staining due to the effects of tetracycline (63). External bleaching can be applied by the dentist or staff or can be applied by the patient in home-use bleaching. When dentist-administered and home-use bleaching are both used, it is called “dual bleaching.”

Dentist-applied external bleaching can be done with periodic repetitions of an office-bleaching agent using Superoxol or 30% H_2O_2 . An etching gel containing phosphoric acid applied to selected dark areas increases the penetration of the bleach. Light is used to produce heat, which accelerates the bleaching process. External bleaching may need additional treatment every 1–2 years to touch up relapses. Severely stained teeth may require more frequent retreatment.

Home bleaching, supervised by the dentist, is done by the patient at home using a custom-made carrier that holds the bleach against the patient's teeth (64). After the desired result is achieved, overnight use on a periodic basis (1–4× month) can maintain the lightening that has been achieved.

External bleaching is seldom permanent, lasting approximately 1–4 years, after which teeth gradually return to their original color. Usually the younger the patient, the longer the bleaching will last. The more difficult it is to bleach a tooth, the more likely it is to discolor again. Bluish–gray stains seem to reappear more quickly than yellow stains. Because reoccurrence of staining is unpredictable, promises about longevity should not be made. Internal bleaching usually lasts longer than external bleaching.

Whitening Formulas

Whitening of teeth can occur by two mechanisms. One method is mechanical, in which an abrasive is used to

remove debris from the tooth. The other method involves either the use of peroxides, which react with water to form free oxygen radicals that help to whiten the teeth or a combination of mechanical and chemical actions. This latter mechanism is found with bleaching agents and is longer lasting than whitening procedures.

XEROSTOMIA

The widely held belief that saliva production significantly decreases with age is not well supported in the literature dealing with this subject. Aging does not appear to play a major role as a single contributing factor in causing xerostomia (65). However, senior citizens may receive medication that produces the side effect of xerostomia. The aged also develop medical problems that can diminish salivary production.

For these reasons, most of the studies of xerostomia have focused on older patients. One study reported a direct correlation between the intake of anticholinergic drugs, sedatives, and hypnotics and xerostomia (66). Over 400 drugs have been identified as potential reducers of salivary flow by acting on the cholinergic (parasympathetic) system either directly or indirectly (67). Another study found that the use of drugs producing xerostomia increases with age and, as expected, is highest in institutionalized patients. There are over 30 classifications of prescription and nonprescription medications that can reduce salivary flow.

Other factors that can cause xerostomia are systemic disorders and radiation (67). These factors must be considered in the differential diagnosis of xerostomia.

Clinical Problems with Xerostomia

Clinical problems associated with reduced salivary flow include difficulty chewing foods, reduced denture retention, recurrent caries, root surface caries, and oral candidiasis (low grade). When any of these conditions are found in a patient, regardless of age, reduced salivary flow should be considered in a differential diagnosis of the problem.

Treatment

Treatment of patients with reduced salivary flow should include the following: (1) drug and dosage changes by the patient's physician in consultation with the patient's dentist; (2) use of artificial saliva in a spray form; (3) use of mouth moisturizers and lip balms; (4) use of sugarless hard

candy; (5) frequent sipping of water; (6) use of decaffeinated products; (7) use of pilocarpine (Salagen) 3–5× daily; and (8) inclusion of citrus and pineapple flavors in the diet.

LOCAL DELIVERY OF ANTIMICROBIAL AGENTS

In the past decade, significant research and product innovations have focused the attention of dental practitioners on the concept of the local application of antimicrobials to treat periodontal diseases. Three local delivery agents are now available in the United States, and two additional products are available in other parts of the world.

Though the rationale of antimicrobial approaches to treatment is evident, their limitations have also been evident. With systemic therapy, it may be difficult to achieve bacteriostatic or bactericidal antibiotic concentrations in pockets without using doses that evoke systemic side effects. The development of bacterial resistance is also an issue. The rise of antibiotic resistant, disease-producing bacterial strains is currently a major public health concern. Prolonged, repetitive courses of antibiotics for recurring dental infections is discouraged, because such practice can more readily lead to the development of resistance (68). Preferably, the cause of the infection should be eliminated rather than merely “managed” with antibiotics. Once antibiotic therapy is initiated, however, the importance of compliance with dosage and duration of treatment must be stressed with the patient. With poor patient compliance, under-dosing may occur, which, in turn, can favor the emergence of resistant bacteria.

Controlled Medication Delivery

The limitations of systemic therapy have prompted extensive research for the development of alternative delivery systems. Local, controlled delivery systems are available to release pilocarpine to the eye for a week after single placement for treatment of glaucoma. The oral cavity offers another relatively accessible disease site for localized therapy. In localized therapy for periodontal disease, the concern is the difficulty in reaching deep pockets and sustaining bacteriostatic or bactericidal levels long enough to be effective but not causing the development of resistance. The following is summary information about the various products available in the United States.

Tetracycline-containing fibers (Actisite®)

The first local delivery product available in the United States, one which has been extensively studied, is an ethylene–vinyl acetate copolymer fiber, diameter 0.5 mm, containing tetracycline, 12.7 mg/9 in. (Actisite tetracycline fiber; manufactured by Alza Corporation, Piscataway, NJ; distributed by Procter & Gamble Co., Cincinnati, OH; Fig. 1). When packed into a periodontal pocket, it is well tolerated by oral tissues, and for 10 days, it sustains tetracycline concentrations exceeding 1300 µg/ml, well beyond the 32–64 µg/ml required to inhibit the growth of pathogens isolated from periodontal pockets (69, 70). In contrast, crevicular fluid concentrations of only 4–8 µg/ml are reported following systemic tetracycline administration, 250 mg, 4× daily for 10 days (total oral dose, 10 g; 68). Thus, controlled site-specific tetracycline delivery can achieve a bactericidal effect at approximately 1/1000th of the dose administered systemically.

Studies demonstrate that the tetracycline fibers, applied with or without scaling and root planing, reduce probing depth, bleeding on probing, and periodontal pathogens and provide gains in clinical attachment level. Such effects are significantly better than those attained with scaling and root planing alone or with placebo fibers. The fibers used in conjunction with scaling and root planing have also provided a statistically significant improvement in probing depth reduction and clinical attachment level gains of over 60% and in bleeding on probing reductions over scaling and root planing alone at 6 months after therapy (71).

Actisite was the first local delivery system cleared by the FDA for the adjunctive treatment of recurrent periodontal disease. Although 6-month studies have demonstrated their value, longer-term studies are needed.

Chlorhexidine delivery system (PerioChip®)

A newer development in controlled local delivery, one that utilizes the antiseptic chlorhexidine as the antimicrobial agent, has been introduced in a number of countries and was recently cleared by the FDA for use in the United States. This delivery system, PerioChip (manufactured by Perio Products Ltd., Jerusalem, Israel; distributed by Dexell Pharmaceuticals, Edison, NJ), was developed in Israel and has been tested in the United States as well as in Europe.

The PerioChip is a small chip (4.0 × 5.0 × 0.35 mm) composed of a biodegradable hydrolyzed gelatin matrix into which has been incorporated 2.5 mg chlorhexidine gluconate per chip. It is rounded on one end and inserts easily and in less than a minute into periodontal pockets that are 5 mm or greater in depth. The PerioChip releases

chlorhexidine and maintains drug concentrations in the gingival crevicular fluid greater than 100 µg/ml for at least 7 days, concentrations well above the tolerance of most oral bacteria (72). Because the PerioChip biodegrades in 7–10 days, a second appointment for removal is not needed. Studies with the PerioChip were as long as 9 months (73). At 9 months, significant decreases were observed in probing depth from baseline favoring the active chip plus scaling and root planing compared with controls (scaling and root planing only): chlorhexidine chip plus scaling and root planing, -0.95 ± 0.05 mm; placebo chip plus scaling and root planing, -0.69 ± 0.05 mm ($p = 0.00056$); scaling and root planing alone -0.65 ± 0.05 mm ($p = 0.00001$). The proportion of pocket sites with a probing depth reduction of 2 mm or more was increased in the chlorhexidine chip group compared with scaling and root planing alone, a difference which was statistically significant on a per patient basis ($p < 0.0001$). Improvements favoring the chlorhexidine chip compared with controls were also observed for clinical attachment levels at 9 months, improvements that were significant when the data were pooled ($p < 0.05$). Bleeding on probing was reduced in the active chip group compared with both controls, differences which were significant in one of the two studies ($p < 0.05$) and when the data were pooled ($p = 0.012$).

The results of these studies suggest that the Perio Chip may be a valuable adjunct to scaling and root planing in the treatment of periodontal disease. This product is easily placed, requires no appointment for removal, and provides reductions in probing depths similar to subgingivally placed antibiotics now available in various countries across the world. In addition, a major advantage of this system is that its active agent is an antiseptic instead of an antibiotic.

Subgingival Delivery of Doxycycline (Atridox®)

Atridox (manufactured by Atrix Laboratories, Fort Collins, CO) is a recently developed gel system that incorporates the antibiotic doxycycline (10%) in a syringeable gel system. An animal study in beagle dogs initially suggested some benefit to locally delivered doxycycline (74), and it is used in the veterinary population.

A recent 9-month, multicenter study was designed to study the effects of subgingivally placed doxycycline compared to subgingival placement of the vehicle and an herbal agent (Sanguinaria; 75). No scaling or root planing was performed in any of the groups, and there was no untreated group. The patients were instructed in oral

hygiene and randomly assigned to one of three groups: vehicle control, 5% sanguinarine in the vehicle control, and 10% doxycycline in the vehicle control.

Treatment with doxycycline was more effective than the other treatments at all time periods, with the exception of the 3-month clinical attachment level value. Also, when the authors evaluated the effect based on initial probing depth, the differential effect in the doxycycline group in comparison with the other two groups was greater as pretreatment probing depth increased. For the doxycycline group, the reduction in clinical attachment level at 9 months showed a gain of 0.4 mm compared to vehicle control, the reduction in probing depth was 0.6 mm greater than vehicle control, and the reduction of bleeding on probing was 0.2 units greater than vehicle control. Although the differences were small, they were statistically significant. The patient's oral hygiene scores (plaque index) averaged between 0.7 and 1.1 in all three groups throughout the study. Although resistance was not evaluated in this study, the local application of doxycycline has previously been reported to show transient increases in resistance in oral microbes and no overgrowth of foreign pathogens (76).

Data have recently been presented from two multicenter clinical trials (77). All treatment groups showed clinical improvements from baseline over the 9-month period. The results for all parameters measured were significantly better in the doxycycline group compared with vehicle control and oral hygiene only. Compared with scaling and root planing, the effects of doxycycline on clinical attachment level gain and probing depth reduction were equivalent.

Clinical study results suggest a potential periodontal benefit from the subgingival application of doxycycline. However, the value of this agent as an adjunct to scaling and root planing is untested. This product is cleared by the FDA for use in animals and humans.

HOST MODULATION

In 1998, the first nonantimicrobial drug to treat periodontal disease, Periostat, was approved by the FDA. Nonetheless, in the antibiotic family, the dose of the drug used is too low to kill bacteria. Periostat acts through its effects on inhibition of metalloproteinases, such as, collagenase and gelatinase. The therapeutic objective is to modulate the inflammatory host response. Periostat, available as a 20 mg capsule of doxycycline hyclate, is prescribed for use by patients twice daily. The mechanism of action is by suppression of the activity of collagenase, particularly that produced by polymorphonuclear leukocytes. Although this

drug is in the antibiotic family, it does not produce any antimicrobial effects because the dose of 20 mg twice daily is too low to affect bacteria. As a result, resistance to this medication cannot develop.

Four double-blind, clinical, multicenter studies in over 650 patients have demonstrated that Periostat improves the effectiveness of professional periodontal care and slows the progression of the disease process (78).

DRUG DELIVERY — LIQUID CRYSTALS IN

Christel C. Mueller-Goymann

*Universität Braunschweig Mendelssohnstr, Braunschweig,
Germany*

DEFINITION AND FORMATION OF LIQUID CRYSTALS

Definition

The liquid crystalline state combines properties of both liquid and solid states. The liquid state is associated with the ability to flow, whereas the solid state is characterized by an ordered, crystalline structure (1). Crystalline solids exhibit short as well as long-range order with regard to both position and orientation of the molecules (Fig. 1a). Liquids are amorphous in general but may show short-range order with regard to position and/or orientation (Fig. 1b). Liquid crystals show at least orientational long-range order and may show short-range order, whereas positional long-range order disappears (Fig. 1c) (2). Accordingly, liquid crystalline phases represent intermediate states and are also called mesophases.

A pre-requirement for the formation of liquid crystalline phases is an anisometric molecular shape that is generally associated with a marked anisotropy of the polarizability. Molecules that can form mesophases are called mesogens. Depending on the molecular shape, rod-like mesogens form calamitic mesophases and disc-like mesogens form discotic mesophases. Rod-shaped molecules are often excipients of drugs (e.g., surfactants). Even drug compounds themselves (e.g., the salts of organic acids or bases with anisometric molecular shape) fulfill the requirements for the formation of calamitic mesophases.

Formation

Starting with the crystalline state, the mesophase is reached either by increasing the temperature or by adding a solvent; accordingly, a differentiation can be made between thermotropic and lyotropic liquid crystals, respectively. As with thermotropic liquid crystals, a variation of temperature can also cause a phase transformation between different mesophases with lyotropic liquid crystals.

Thermotropic liquid crystals

Calamitic mesophases were the first liquid crystals to be found more than 100 years ago. In 1888, the botanist

Friedrich Reinitzer observed birefringence of cholesteryl esters after melting (3) and contacted the physicist Otto Lehmann, a specialist in crystallization microscopy, who interpreted the birefringence of the molten cholesteryl esters as a parallel orientation of molecules within a liquid crystal, a new kind of state (4). However, these cholesteric liquid crystals exhibit not only a parallel orientation of the anisometric molecules, but the director of the orientation rotates layer by layer in a right- or left-handed helix (Fig. 2b). The layer distance where a 360° rotation has been performed is called pitch, which is often in the magnitude of the visible light. This phenomenon, as well as the variation of pitch with temperature, is responsible for the characteristic color play of cholesteric liquid crystals. Cholesterics require chirality either of the mesogen itself or on addition of a mesogen.

The nematics are similar to cholesteric liquid crystals in having just orientational long-range order, with the deviation that the director of the preferred orientation does not rotate (Fig. 2a). If, however, a chiral mesogen is dissolved in a nematic liquid crystal, the latter will transform into a cholesteric liquid crystal.

Calamitic mesophases with parallel orientation of the molecules, which are additionally arranged in layers, are called smectic liquid crystals (Fig. 2c-e). The layer plane may be oriented either perpendicular or tilted to the long axes of the molecules. Furthermore, the molecules may be arranged regularly within the layer (e.g., in a hexagonal arrangement), thus forming a three-dimensional lattice. As opposed to crystals, the smectic liquid crystalline state enables rotation of the molecules around their long axes. Different smectics may be distinguished in the basis of a variety of arrangements.

Phase transitions occur with increasing temperature, for example, crystalline to smectic C to smectic A to nematic to isotropic, or crystalline to nematic to isotropic. These examples demonstrate that not all possible transitions necessarily occur. Depending on the number of mesophases occurring, thermotropic mono-, di-, tri-, or tetra-morphism may be distinguished.

Discotic liquid crystals arise from disc-shaped molecules as nematic or cholesteric mesophases. Their

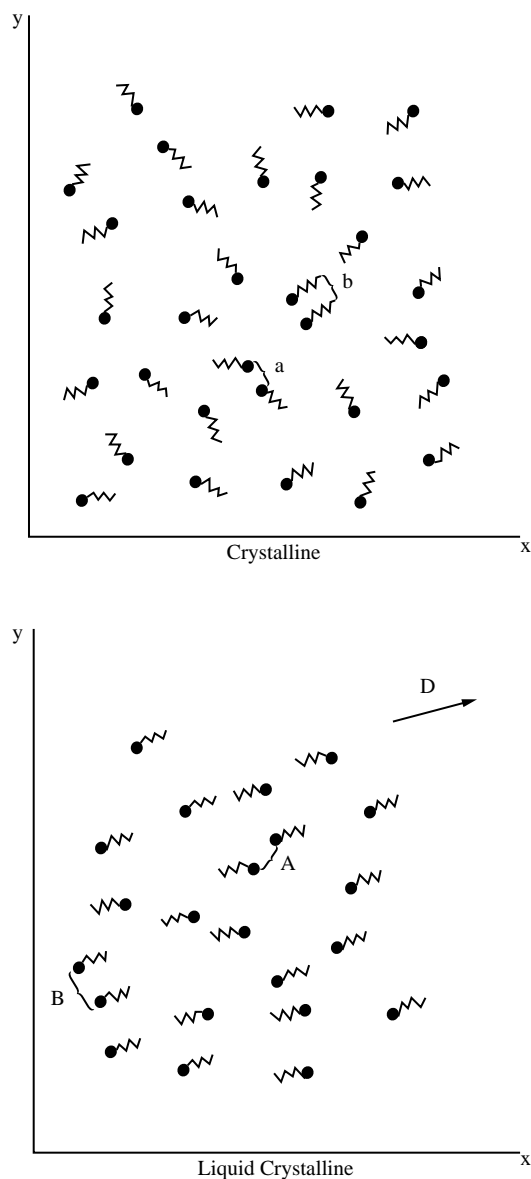

Fig. 1 Two-dimensional representation of short-range order (a, b) and long-range order (A, B) in the crystalline and liquid crystalline states. (From Ref. 2.)

structural characteristics are similar to that of their respective calamitic mesophases, that is, the normals of the discs are oriented parallel. Instead of the smectic mesophases, discotic columnar liquid crystals arise from stapling the discs one on the other. The columns of the discotic columnar mesophase form a two-dimensional lattice that is in either a hexagonal or a rectangular modification. In addition, the columns may or may not be tilted (Fig. 2f and 2g).

Lyotropic liquid crystals

Lyotropic liquid crystals differ from thermotropic liquid crystals. They are formed by mesogens that are not the molecules themselves but their hydrates or solvates as well as by associates of hydrated or solvated molecules. In presence of water or a mixture of water and an organic solvent as the most important solvents for drug molecules, the degree of hydration or solvation depends on the amphiphilic properties of a drug molecule. Hydration—and solvation—of the mostly rod-shaped molecule results in different geometries such as cone and cylinder (Fig. 3) (7).

Fig. 3 Geometry of hydrated molecules—cylinders associate to a lamellar liquid crystal, cones to a hexagonal and an inverse hexagonal one. (Adapted from Ref. 7.)

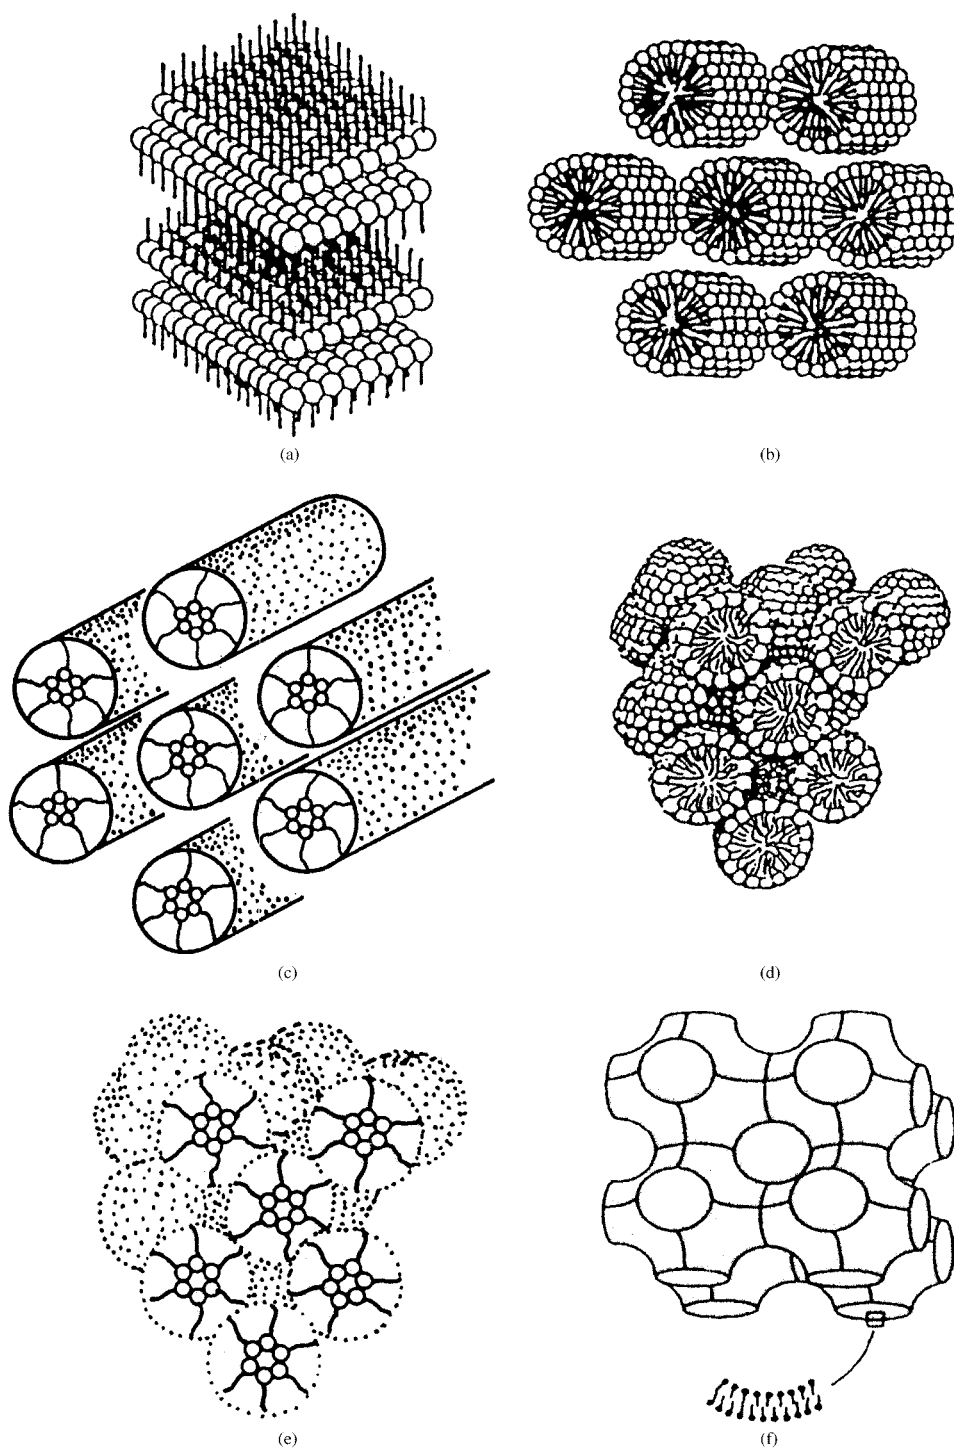

Fig. 4 Molecular structure of lyotropic liquid crystals. (a) lamellar; (b) hexagonal; (c) inverse hexagonal; (d) cubic type I; (e) inverse cubic type IV; (f) cubic type II. (a, b, and d: Adapted from Ref. 8; c: Adapted from Ref. 9; e: Adapted from Ref. 10; f: Adapted from Ref. 11.)

Cylinders arrange in layers; this results in a lamellar phase with alternating polar and nonpolar layers (Fig. 4a). Water and aqueous solutions can be included in the polar layers, resulting in an increase of layer thickness. Analogously, affinic molecules can be included in the nonpolar layers. In addition to the increased layer thickness of the lamellar phase, lateral inclusion between molecules is also possible with an increase in the solvent concentration, which transforms the rod shape of the solvated molecules to a cone shape (Fig. 3), thereby leading to a phase change. Depending on the polar or nonpolar character of the solvating agent and the molecule itself, the transition results in a hexagonal or an inverse hexagonal phase (Figs. 4b and 4c).

The hexagonal phase is named after the hexagonally packed rod micelles of solvated molecules, whereby their polar functional groups point either to the outside (Fig. 4c) or to the inside of the structure (Fig. 4, inverse hexagonal phase). In the hexagonal phase, the additional amount of water or unpolar solvent that can be included is limited. As the molecular geometry changes further during solvation, another phase transformation to a cubic form (type I) or inverse cubic form (type IV) takes place, consisting of spherical or ellipsoidal micelles and/or inverse micelles (Figs. 4d and 4e).

In addition to the cubic and/or inverse cubic forms described previously, further transitional forms exist between the lamellar phase and the hexagonal mesophase (cubic, type II) or inverse hexagonal mesophase (cubic, type III) (12). In contrast to the discontinuous phases of types I and IV, cubic mesophases of type II and type III belong to the bicontinuous phases (Fig. 4f). A range of lyotropic mesophases are possible, depending on the mesogen concentration, the lipophilic or hydrophilic characteristics of the solvent and the molecule itself (Table 1). However, not all theoretically possible mesophases may occur in practice.

Liposomes

With some molecules, a high concentration results in a lamellar phase, but no additional mesophases are formed if the concentration is reduced. The lamellar phase is dispersed in the form of concentric-layered particles in an excess of solvent (water or aqueous solution). This results in a vesicular dispersion. If the mesogenic material consists of phospholipids, the vesicular dispersion is called a liposomal dispersion (13). In principle, liposomes may be dispersed in oily continuous media too. However, the latter systems are of minor interest in drug formulation.

Liposomes consist of many or only few phospholipid bilayers, or just one bilayer (Fig. 5). Based on this, multilamellar vesicles (MLV), oligolamellar vesicles (OLV), small unilamellar (SUV), and large unilamellar vesicles (LUV) can be distinguished. Furthermore, multi-vesicular liposomes (MVL) may be formed.

The polar character of the liposomal core enables the encapsulation of polar drug molecules. Amphiphilic and lipophilic molecules are solubilized within the phospholipid bilayer depending on their affinity for the phospholipids. Participation of nonionic surfactants instead of phospholipids in the bilayer formation results in NiosomesTM. The term sphingosomes is suggested for vesicles from sphingolipids. However, nomenclature is not consistent; the term liposomes is used as a general term, although vesicles would be a better term.

A standard manufacturing procedure of liposomes is the film-forming method. Prior to film formation, the phospholipids are dissolved in an organic solvent. By rotational evaporation of the solvent, a thin multilayered film of phospholipids develops at the inner wall of the vessel. Redispersion of this film in water or aqueous buffer results in the formation of vesicles. The size of the vesicles and the number of bilayers vary. Hence, further manufacturing steps are needed to obtain defined vesicular dispersions with a sufficient shelf-life.

To reduce vesicle size and the number of bilayers, high-pressure filtration via polycarbonate membranes or high-pressure homogenization in a French press or in a microfluidizer are appropriate manufacturing procedures. Sonication may also be applied, although the obtained dispersion does not have the same particle sizes.

Alternatively, injection method and reverse-phase dialysis are appropriate procedures for the formation of SUV and LUV. Freeze-thaw procedures enable drug loading of the liposomes and also offer an evaluation of the stability of the vesicular dispersion. For interested readers, general reading is recommended (13, 14).

Liquid Crystal Polymers (LCP)

Both thermotropic and lyotropic liquid crystal polymers exhibit characteristic features with regard to their microstructure (15, 16). Anisometrical monomers such as rods or discs are connected to chains in an appropriate manner. These anisometrical monomers are considered to be the mesogens and may be part of main chain LCP, side chain LCP, or of both types together (Fig. 6). Between the mesogens are located flexible spacers of nonmesogenic character. Sufficient flexibility is a prerequisite for liquid crystal formation, with an increase in either temperature or solvent concentration.

METHODS FOR CHARACTERIZATION OF LIQUID CRYSTALS

Methods appropriate for the investigation and characterization of lyotropic liquid crystals are frequently used in drug development and may thus be employed in pharmaceutical laboratories. These methods are both macroscopic and microscopic.

Polarized Light Microscopy

Lyotropic liquid crystals except for cubic mesophases show birefringence just like real crystals do. Birefringence can be observed in a polarization microscope. Two polarizers in cross position are mounted below and above the birefringent object being examined. The cross position of the polarizers provides plane polarized waves perpendicular to each other. Therefore, the light passing the polarizer below an isotropic object cannot pass the polarizer in across position above the object. In an anisotropic material, some parts of the light are able to pass the second polarizer because the plane polarized beam has been rotated by an angle relative to the plane of the incoming beam.

Each liquid crystal shows typical black and white textures. The addition of an λ-plate with strong birefringent properties enables the observation of color effects of the textures in yellow, turquoise, and pink. Color effects arise because rotation of the plane polarized light depends on wavelength. The thickness of the λ-plate is suited for a wavelength of 550 nm. After leaving the plate, this wavelength swings in the same plane as the incoming polarized white light does. Therefore, it is totally absorbed by the second polarizer in the cross position. All the other wavelengths of the white light except for the 550-nm one are more or less rotated with respect to the polarization plane. Hence they pass the polarizer with various intensities. White light minus the 550-nm wavelength (green yellow) gives the impression of a pink color. With an additional

Fig. 5 Schematic cross sections of vesicles, each line represents a bilayer of hydrated molecules. (From Ref. 2.)

birefringent liquid crystalline material in the microscope, small deviations of the wavelengths being absorbed occur; thereby, turquoise and yellow textures can be observed.

Hexagonal mesophases can be recognized by their typical fan-shaped texture (Fig. 7a). Lamellar mesophases typically show oily streaks with inserted maltese crosses (Fig. 7b). The latter result from defects, so-called confocal domains, that arise from concentric rearrangement of plane layers. These defects prevail in some lamellar mesophases. Hence, no oily streaks occur but maltese crosses are the dominant texture (Fig. 7c).

The smectic mesophases of the thermotropic liquid crystals show a variety of textures but resemble the fan-shaped texture of the lyotropic hexagonal mesophase. More comprehensive literature is recommended for further reading (5).

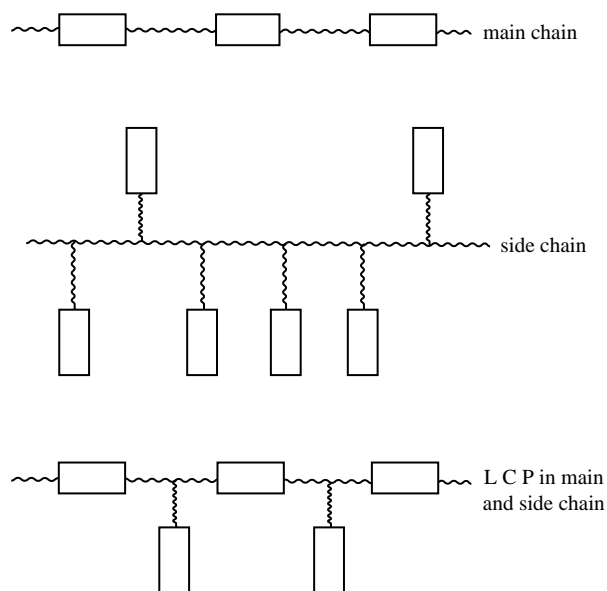

Fig. 6 Liquid crystal polymers with the mesogen within the main chain, the side chain and both the main and side chain, respectively. (From Ref. 2.)

Transmission Electron Microscopy (TEM)

Due to the high magnification power of the electron microscope, the microstructure of liquid crystals can be visualized. However, aqueous samples do not survive the high vacuum of an electron microscope without loss of water and thus their microstructure changes. Therefore, special techniques of sample preparation are necessary prior to electron microscopy. The freeze fracture technique has proven to be successful in this regard (Fig. 8). For this purpose, a replicum of the sample is produced and viewed in the electron microscope. To preserve the original microstructure of the sample during the replication, the first step is shock freeze the sample. For high freezing rates to ($10^5 - 10^6$ K/s), the sample is sandwiched as a thin layer between two gold plates and then shock frozen with either nitrogen-cooled liquid propane at -196°C or slush nitrogen at -210°C . If the temperature of the cooling medium is far below its boiling temperature, an efficient freezing rate can be obtained.

The frozen sample within the sample holder is transduced into the recipient of a freeze fracture apparatus, in which the fracture is performed at a temperature of -100°C and a vacuum between 10^{-6} and 5×10^{-7} bar. Within a homogeneous material, the fracture occurs by randomly because all structural elements have equal probabilities for fracturization. However, even a

(a)

(b)

(c)

Fig. 7 Polarized light micrographs of (a) hexagonal; (b) and (c) lamellar liquid crystals. Bar $50 \mu\text{m}$. (From Ref. 17.)

homogeneous material often consists of more or less polar areas. Within polar areas, stronger interactions via hydrogen bonds prevent the fracture; thus, fracture within polar areas is less probable than is fracture within apolar areas. Therefore, the sample profile obtained after

Fig. 8 Freeze fracture replication technique for transmission electron microscopy (TEM). (From Ref. 18.)

fracturization represents the microstructure of the sample just qualitatively and not quantitatively.

Immediate etching after freeze fracture provides sublimation of nonpermanent constituents (commonly ice), with the effect that level differences in the sample surface appear more pronounced.

Following this, the sample surface is shadowed with 2-nm thick platinum under an angle of 45° . Additional vertical shadowing with a 10-times thicker carbon layer of 20-nm platinum provides a high mechanical stability of the replicum, which means easier handling as regards removing, cleaning, drying, and finally observing in the transmission electron microscope (TEM).

The shadowing with platinum under an angle of 45° provides differences in contrast because platinum precipitation takes place preferably at sample positions that face the platinum source in luff whereas sample positions in lee are less or not shadowed. In the TEM, these different thicknesses of platinum absorb the electron beam to different extents, thus forming shadows. This phenomenon results in the formation of a plastic impression of the transmission electron micrographs of the replicum.

Fig. 9a–c represents transmission electron micrographs of different lyotropic liquid crystals after freeze fracture without etching. The layer structure of the lamellar mesophase, including confocal domains, hexagonal arrangement of the rod-like micelles within the hexagonal mesophase, and close by packed spherical micelles within the cubic liquid crystal can be clearly seen.

Fig. 9d and e shows aqueous dispersions of vesicles. The smaller the vesicle, the less probable is an upcoming cross fracture. Thus the question of whether the vesicle is uni- or multilamellar can probably not be answered. At least for the fluid vesicle dispersions, it is possible to solve the problem using cryo-TEM.

For this purpose, it is necessary to give sufficient contrast to a thin film of the frozen sample by using, for example, osmium tetroxide. Then the sample can directly be viewed in the TEM (at a temperature of -196°C). The adjustment of the temperature to -196°C provokes a very low vapor pressure, especially of water, so that the examination of the probe is possible by preservation of the microstructure despite the high vacuum. A disadvantage of cryo-TEM is the classification of vesicles according to their size. Due to the fluid property of vesicle dispersion prior to freezing, the thickness of the sample film varies from the center to the outside. Hence, smaller vesicles stay in the center, where the film is thin, whereas the larger ones linger at the outside margin in the thicker part of the film. In this outer part the vesicles escape detection. Hence the resulting distribution does not represent the actual size distribution.

Fig. 10 Schematic representation of the reflection conditions according to Bragg's equation.

X-ray Scattering

With X-ray scattering experiments, characteristic interferences are generated from an ordered microstructure (23). A typical interference pattern arises due to specific repeat distances of the associated interlayer spacing d . By Bragg's equation, d can be calculated as $d = n(\lambda/2)\sin \vartheta$ where λ is the wavelength of the X-ray (e.g., 0.145 nm by using a copper anode or 0.229 nm by using a chromium anode), n is an integer and denotes the order of the interference and, ϑ is the angle under which interference occurs (i.e., reflection conditions are fulfilled). (See Fig. 10 for a further illustration).

Bragg's equation points at the inverse proportionality between d and ϑ . Large terms for d in the region of long-range order are registered by the small-angle X-ray diffraction technique (SAXD), whereas small terms for d in the region of short-range order are registered by the wide-angle X-ray diffraction technique (WAXD). SAXD is important for the exact determination of the distances of d of liquid crystalline systems. With WAXD, the loss of short-range order of liquid crystalline systems can be recognized in terms of the absence of interferences, which are characteristic of the crystalline state.

Interferences can be detected in two ways: (i) the film detection; and (ii) the registration of X-ray counts with scintillation counters or position-sensitive detectors.

However, SAXD does not only detect interferences from which the interlayer spacings can be calculated, but also enables to decide from the sequence of the interferences the type of liquid crystal (24, 25).

The sequence of the interferences for different liquid crystals is as follows:

Lamellar: $1 : 1/2 : 1/3 : 1/4 \dots$

Hexagonal: $1 : 1/\sqrt{3} : 1/\sqrt{4} : 1/\sqrt{7} \dots$

Cubic: $1 : 1/\sqrt{2} : 1/\sqrt{3} : 1/\sqrt{4} \dots$

Cubic: $1 : 1/\sqrt{4} : 1/\sqrt{5} : 1/\sqrt{6} \dots$

Differential Scanning Calorimetry (DSC)

Phase transitions go along with changes in energy content of the respective system. This phenomenon is caused by changing either the enthalpy ΔH or the entropy ΔS . Enthalpy changes cause endothermic or exothermic signals depending on whether the transition is due to consumption of energy (e.g., melting of a solid) or release of energy (e.g., recrystallization of an isotropic melt).

It should be mentioned that the transition from crystalline to amorphous requires much energy, whereas the transition from crystalline to liquid crystalline, from liquid crystalline to amorphous, and particularly the transition between different liquid crystals consume low amounts of energy. Therefore, care has to be taken about the appropriate sensitivity of the measuring device as well as on a sufficiently low detection limit (26).

Entropically caused phase transitions may be recognized by a change in baseline slope according to a change in the specific heat capacity. In particular, the phase transitions of liquid crystalline polymers result from entropic reasons, thus being considered transitions of the second order. These are usually called glass transitions. They can be overlaid from an enthalpic effect so that their detection might be complicated.

Rheology

Different types of liquid crystals exhibit different rheological properties (27, 28). With an increase in the microstructural organization of the liquid crystal, its consistency increases and the flow behavior becomes more viscous. The coefficient of dynamic viscosity η , although a criterion for the viscosity of just ideal viscous flow behavior (Newtonian systems), is rather high for cubic and hexagonal liquid crystals but fairly low for lamellar ones; however, the flow characteristics are not Newtonian but plastic for cubic and hexagonal crystals or pseudoplastic for lamellar ones.

For thermotropic liquid crystals, the viscosity increases in the following sequence:

nematic < smectic A < smectic C.

The low flowability of lyotropic liquid crystals such as cubic and hexagonal mesophases is due to their three-dimensional and two-dimensional order, respectively. Lamellar mesophases with one-dimensional long-range order have a fairly high flowability. Due to their gel character, cubic and hexagonal mesophases even exhibit a yield stress until flow occurs. Unlike the corresponding

inverse liquid crystals, the gel character is much more pronounced because of the interactions between polar functional groups located at the surface of the associates. Via polar interactions, for example hydrogen bonds, the associates may form strong networks with each other. On the other hand, the surface of the associates of inverse mesophases consists of apolar groups of the associated molecules. Thus the resulting interactions are less strong and the gel can get deformed more easily.

A mechanical oscillation measurement is the method of choice for determining the elasticity of liquid crystalline gels. Without applying a superposition of shear strain, the viscoelastic properties of liquid crystals may be studied without a change in network microstructure, which usually occurs in terms of mechanical deformation with rheological investigations. With the oscillation experiments, the viscoelastic character of cubic and hexagonal mesophases as well as that of lamellar mesophases and highly concentrated dispersions of vesicles (which also show viscoelastic behavior) can be quantified. A vesicle dispersion of low content of the inner phase, however, exhibits an ideal viscous flow property. According to the Einstein equation, η is larger than η_0 of the continuous phase, which is usually pure water or solvent, by the multi factor $2.5 \times$ volume ratio of the dispersed phase ϕ .

$$\eta = \eta_0(1 + 2.5\phi)$$

where η_0 = viscosity of pure solvent (i.e., the continuous phase) and, ϕ = volume ratio of the inner phase.

Determination of Vesicle Size by Laser Light Scattering

Vesicle size is an important parameter in not only in-process control but particularly quality assurance because the physical stability of the vesicle dispersion depends on particle size and particle size distribution. An appropriate and particularly quick method is the laser light scattering (for particle size) or diffraction (for particle size distribution). Laser light diffraction can be applied for particles $>1 \mu\text{m}$ and according to the diffraction theory of Fraunhofer, refers to the proportionality between intensity of diffraction and the square of particle diameter.

Rayleigh's theory holds for particles $<200 \text{ nm}$, which considers scattering intensity to be proportional to the sixth potency of the particle diameter. Both Fraunhofer's and Rayleigh's theories are only approximations of Mie's theory, which claims that scattering intensity depends on the scattering angle, absorption, and size of the particles

as well as on the refractive indices of both the particles and the dispersion medium. Unfortunately, the latter parameters are difficult to be determined. Furthermore, most vesicle dispersions consist of a dispersed mesophase with particle sizes $<200 \text{ nm}$ up to $1 \mu\text{m}$. Therefore, photon correlation spectroscopy (PCS) that is based on laser light scattering provides an appropriate method of investigation (29).

Dynamically raised processes in the dispersion, such as Brownian molecular motion, cause variations in the intensities of the scattered light with time, which is measured by PCS. Smaller the particle, higher the fluctuations by Brownian motion. Thus, a correlation between the different intensities measured is only possible for short time intervals. In a monodisperse system following first-order kinetics, the autocorrelation function decreases rather fast. In a half logarithmic plot of the autocorrelation function, the slope of the graph enables the calculation of the hydrodynamic radius by the Stokes–Einstein equation. With the commercial PCS devices the z -average is determined, which corresponds to the hydrodynamic radius.

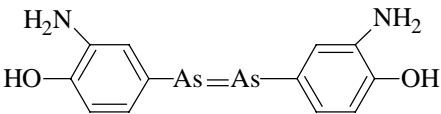

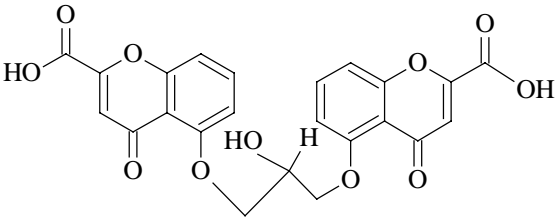

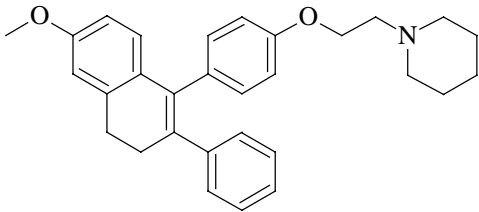

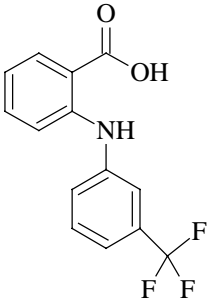

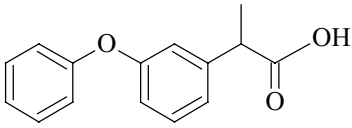

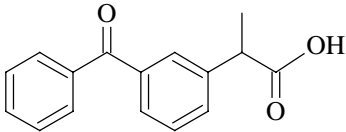

In a polydisperse system, the calculation of particle size distribution is possible, in addition, by using special transformation algorithms. For this, certain requirements need to be fulfilled: a spherical particle shape, sufficient dilution, and a large difference between the refractive indices of the inner and outer phase. As not all requirements can be usually fulfilled, the z -average as a directly accessible parameter is preferred to the distribution function depending on models.

APPLICATIONS OF LIQUID CRYSTALS IN DRUG DELIVERY

Liquid Crystalline Drug Substances

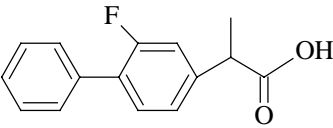

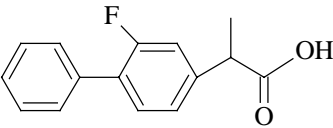

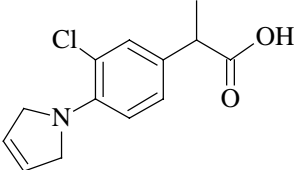

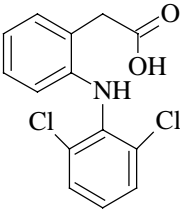

Some drug substances are able to form mesophases either with solvent or alone (30–37). In the latter case, an increase in temperature causes transition from the solid state to the liquid crystalline one. This is called thermotropic mesomorphism. Lyotropic mesomorphism occurs in combination with a solvent, usually water. Furthermore, a change in temperature may cause additional transitions. Thermotropic and/or lyotropic liquid crystalline mesophases of drug substances may interact with mesomorphous vehicles as well as with liquid crystalline structures in humans. Table 2 presents drug substances for which either thermotropic or lyotropic mesomorphism has been proven.

Table 2 Liquid crystalline drug substances

Drug	Type of liquid crystal	Formula	Reference
Arsphenamine	Nematic		30
Disodium cromoglicate	Nematic, hexagonal		31
Nafoxidin-HCl	Hexagonal, cubic, lamellar		32
Diethylammonium flufenamate	Lamellar		33
NSAID salts Fenoprofen	Lamellar		34
Ketoprofen	Lamellar		34

(Continued)

Table 2 Liquid crystalline drug substances (*Continued*)

Drug	Type of liquid crystal	Formula	Reference
Ibuprofen	Lamellar		34
Flurbiprofen	Lamellar		34
Pirprofen	Lamellar		34
Diclofenac	Lamellar		36
Peptide hormone	LH-RH analogue		35

Arsphenamin was the first drug substance with thermotropic mesomorphism (30) to be therapeutically used as Salvarsan during the first half of the nineteenth century. The drug is effective against microorganisms and thus offered for the first time an efficient therapy of venereal diseases such as syphilis. Nowadays, it has been replaced by antibiotics with less serious side effects.

The molecular structure of arspenamin is typical of a thermotropic mesogen. With its symmetrical arrangement of atoms, the same holds for disodium cromoglicinate (DNCG) (30), which forms thermotropic liquid crystals and additionally lyotropic mesophases with water. If micronized DNCG powder is applied to the mucosa of the nose or the bronchi, the powder will absorb water from the high relative humidity of the respiratory tract, and first transform into a lyotropic mesophase and then into a solution.

DNCG serves as a mast-cell stabilizer. Mast cells are located on the mucosa of the respiratory tract and act by

releasing the mediator substance histamine on contact with an allergen, provided the patient had been sensitized previously. Due to its mast-cell stabilizing effect, DNCG acts as a prophylactic against allergic reactions associated with asthma and hay fever. In addition to this prophylactic effect, DNCG exhibits a second mode of action in causal therapy of asthma, which has not yet been fully clarified. According to recent findings, DNCG has a positive effect on the inflammation of the mucosa of bronchi.

For therapeutic purposes, a similar frequently used group of drug compounds is the nonsteroidal anti-inflammatory drugs (NSAIDs). One of the best known representatives of the aryl acetic acid derivatives is diclofenac and that of aryl propionic acid derivatives is ibuprofen. As both have acidic properties, they dissociate while being dissolved and may form salts with amphiphilic properties. Together with appropriate

(a)

(b)

Fig. 11 Transmission electron micrographs of freeze fractured oily droplets dispersed in (a) a hexagonal and (b) a cubic liquid crystalline phase, bar represents 100 nm. (From Ref. 38.)

counter ions, these amphiphilic organic acids may form lyotropic mesophases with water at even room or body temperature e.g., diclofenac diethylamine or ibuprofen lysinate (34, 36). Furthermore, some anhydrides of NSAID, e.g., fenoprofen calcium (37), exhibit thermotropic mesomorphism after thermal dehydration of the crystalline salt.

All the other drugs substance listed in Table 2 have not yet been used for therapeutical purposes.

Liquid Crystalline Formulations for Dermal Application

As long as drug molecules with amphiphilic character form lyotropic mesophases, amphiphilic excipients in drug formulations form lyotropic liquid crystals. Especially surfactants, which are commonly used as emulsifiers in dermal formulations, associate to micelles after dissolution

Fig. 12 Permeability of ibuprofen from different formulations via excised human stratum corneum. (Redrawn from Ref. 39.)

in a solvent. With increasing concentration of these micelles, the probability of interaction between these micelles increases, forming liquid crystals.

Surfactant gels

The use of monophasic systems of lyotropic liquid crystals is relatively seldom and is limited to gels. A variety of polar surfactants (e.g., ethoxylated fatty alcohols) are hydrated in presence of water and form spherical or ellipsoidal micelles. At high surfactant concentrations, these associates are densely packed and are thus identified as cubic liquid crystals (20).

Fig. 9c represents a transmission electron micrograph of a liquid crystalline surfactant gel of this type. Such gels are optically transparent. If agitated mechanically, their elastic properties become evident. Due to resonance effects in the audible range, they are also called ringing gels. The lipophilic components are solubilized together with the active ingredients in hydrated associates of the surfactants. However, the solubilization capacity for lipophilic components is generally limited. By exceeding this capacity, the excess of the lipophilic component will be dispersed dropwise in the liquid crystalline phase (Fig. 11b). Such systems exhibit a white appearance according to the change in refractive index at the interface between continuous liquid crystalline and dispersed oil phase. Besides, the dispersed drops are mechanically stabilized because the liquid crystalline phase of either hexagonal (Fig. 11a) or cubic character (Fig. 11c) has a high yield stress.

Ringing gels with cubic liquid crystalline microstructure are used as commercial drug formulations especially for topical NSAID formulations. Examples in the German market include Contrheuma Gel Forte N, Trauma-Dolgit Gel, and Dolgit Mikrogel. Dolgit Mikrogel was introduced in 1996 and contains ibuprofen as an active ingredient. On the one hand the high surfactant concentration of such gels

is necessary to verify the liquid crystalline microstructure; on the other hand, this concentration influences the microstructure of the stratum corneum lipids via increase in permeability. This effect is also achieved by alcohol, which is also solubilized in the formulation. Fig. 12 shows the result of permeation tests with excised human stratum corneum. The amount of ibuprofen permeating per unit time and surface area is much higher for Dolgit Mikrogel than for an aqueous mixed micellar solution of the drug. Although relatively high permeation rates are possible for the liquid preparation, the commercial formulation is significantly more effective because the high surfactant content and the alcohol favor high permeability.

A ringed surfactant gel of liquid crystalline microstructure containing the antimycotic bifonazole (Bifomyk gel) was introduced in 1995 into the German market. Similar to surfactant gels containing NSAID, an improved penetration of the active ingredient is desired in antifungal therapy of the dermis as well. However, because the liquid crystal structure only forms with a relatively high surfactant concentration, the positive effect of improved penetration must be considered together with the potential of irritation. The objective is to achieve improved penetration with minimum irritation, via a change in skin structure. Because hyphae fungal (mycelium) can penetrate deep into the epidermal layers by sliding past corneocytes of the horny layer, improvement of antimycotic therapy is of particular importance. The same holds true for penetration of NSAIDs through several epidermal layers because they have to arrive at the deeply located muscle and joint tissue.

Fig. 13 Transmission electron micrograph of a freeze fractured w/o cream. The aqueous phase is dispersed as droplets within the continuous lipophilic phase and the interface consists of multiple bilayers of hydrated surfactant molecules; bar 500 nm. (From Ref. 41.)

Ointments and creams

Usually the surfactant concentration in ointments and creams is significantly lower than in surfactant gels. Ointments are nonaqueous preparations, whereas creams result from ointments by adding water. The microstructure of both ointments and creams may consist of liquid crystals, as long as a liquid crystalline network or matrix is formed by amphiphilic molecules. In a liquid crystalline matrix, it is easier to deform the system by shear; such formulations show plastic and thixotropic flow behavior on shear. In comparison to systems with a crystalline matrix which are usually destroyed irreversibly by shear, those with a liquid crystalline matrix exhibit a short regeneration time of the sheared matrix. To obtain a liquid crystalline matrix, amphiphilic surfactants, that form lyotropic liquid crystals at room temperature have to be selected. Preferably, lamellar liquid crystals that are able to solubilize high amounts of further ingredients and spread through the whole formulation as a network-forming crosslinked matrix should be formed. In contrast, ointments that contain long-chain fatty alcohols such as cetyl and/or stearyl alcohol have a crystalline structure at room temperature (40).

Although the so-called α -Phase of the fatty alcohols—a thermotropic type smectic B liquid crystal with hexagonal arrangement of molecules within the double layers—is initially formed from the melt during the manufacturing process, it normally transforms into a crystalline modification as it cools. However, the crystallization of the gel matrix can be avoided if the α -Phase can be kept stable as it cools to room temperature. This can be achieved by combining appropriate surfactants such as myristyl or lauryl alcohol and cholesterol, a mixture of which forms a lamellar liquid crystal at room temperature (41). Due to depression of the melting point, the phase transition temperature of crystalline to liquid crystalline as well as liquid crystalline to isotropic decreases. Therefore, a liquid crystalline microstructure is obtained at room temperature.

The polar character of a surfactant molecule enables the addition of water to form creams. Depending on whether the surfactant or the surfactant mixture has a strong or weak polar character, creams of type o/w or w/o are formed. Creams of w/o type are produced from systems that are stabilized solely with weakly polar surfactants such as fatty alcohols, cholesterol, glycerol monostearate, or sorbitan fatty acid esters. The surfactant or surfactant mixtures are adsorbed at the interface of the dispersed aqueous and the continuous lipophilic phase. Even multiple layers of the surfactant will be adsorbed if the concentration of mesogenic molecules is

high enough to form their own liquid crystalline phase (Fig. 13). Apart from the reduction of surface tension and/or surface energy, the liquid crystalline interface also has a mechanically stabilizing effect on the emulsion drops.

Surfactants such as sulfated fatty alcohols may be hydrated to a higher extent than the fatty alcohols alone, and thus stabilize o/w emulsions. The combination of an anionic and a nonionic surfactant has proven to be particularly effective, as the electrostatic repulsion forces among the ionic surfactant molecules at the interface are reduced by the incorporation of nonionic molecules, thereby improving emulsion stability. The combination of cetyl/stearyl sulfate (Lanette E) and cetyl/stearyl alcohol (Lanette O) to yield an emulsifying cetyl/stearyl alcohol (Lanette N) is an example of this approach. The polar properties of this surfactant mixture are dominant; therefore, o/w creams are formed. In contrast to w/o systems, the stabilizing effect of the surfactant mixture is not mainly due to adsorption at the interface. Instead, the mixed surfactants are highly hydrated and form a lamellar network, which is dispersed throughout the continuous aqueous phase, whereas the dispersed lipophilic components are immobilized within the gel network. However, this hydrated gel matrix is not crystalline at room temperature as are the corresponding w/o creams with cetyl/stearyl alcohol, but is in its α -phase, which belongs to the thermotropic smectic liquid crystals and exhibits a strong similarity to lyotropic lamellar liquid crystals.

Analogous gel matrices of liquid crystalline lamellar phases can also be formed with nonionic mesogens, for example, with the combination of cetyl/stearyl alcohol and

ethoxylated fatty alcohol, provided the hydrophilic and lipophilic properties of the surfactant molecules are more or less balanced to favor the formation of lamellar structures.

Liposome Dispersions

Although liposomes have been extensively studied since 1970, only a few commercial drug formulations contain liposomes as drug carriers (42, 43). The first commercial drug formulation with liposomes for topical administration was registered in Italy. The antimycotic econazol was encapsulated in liposomes being dispersed in a hydrogel (Ecosom Liposomengel, formerly Pevaryl Lipogel). Due to the formation of a highly hydrated gel network of the hydrophilic polymers, liposomes are immobilized within the gel network and thus mechanically stabilized. This stabilization via gelation of the continuous aqueous phase can also be applied to other dispersion systems (e.g., suspensions or emulsions). An example of such an emulsion/hydrogel combination that contains heparin sodium as an active ingredient and liposomes as the additional dispersed phase (the latter only since 1995) is Heparin Liposom. A formulation with an analogous emulsion/hydrogel combination but without additional liposomes is Voltaren Emulgel. The transmission electron micrograph (Fig. 14) reveals an adsorption of lamellar liquid crystals at the interface of dispersed oil drops and the aqueous continuous phase. The aqueous continuous phase is again a hydrogel based on polyacrylate in which the lipophilic phase is immobilized. The interface consists of multilamellar layers consisting of both surfactant and drug molecules. Thus the hydrogel is not only stabilized by the hydrogel network itself but also by the liquid crystalline interface, which provides an additional stabilization. The active ingredient diclofenac diethylamine diffuses slowly from the dispersed phase via the multilamellar interface into the continuous phase, from where it penetrates into the epidermis.

Similar to Voltaren Emulgel, oily droplets of an eutectic mixture of lidocaine and prilocaine are dispersed in a hydrogel to provide local anaesthesia of the skin for injections and surgical treatment (Emla cream). A further possibility is the dermal administration of a liposome dispersion as a spray (Heparin PUR ratiopharm Sprühgel). After administration, water and isopropyl alcohol evaporate partially to result in an increase of concentration and thereby in a transition from the initial liposome dispersion to a lamellar liquid crystal (45). The therapeutic effect thus appears to be influenced favorably by the presence of lecithins alone, rather than by the degree of dispersion of liposomes.

Fig. 14 Transmission electron micrograph of Voltaren Emulgel. The interface between the continuous hydrogel and the dispersed emulsion droplets consists of multiple bilayers of hydrated surfactant molecules bar 500 nm. (From Ref. 44.)

Liposome dispersions for parenteral administration

Depending on their size and surface charge, parenterally administered liposomes interact with the reticulo endothelial system (RES) and provoke an immunological response. After being marked by the adsorption of certain serum proteins, called opsonins, they are identified as an invader and destroyed by specific immune cells mainly in the liver, spleen, and bone marrow.

This passive drug targeting enables an efficient therapy of diseases of these organs or their affected cells. Clinical tests in the therapy of parasitic diseases of the liver and spleen have proven most efficient by having encapsulated the drug substance in liposomes. Apart from passive drug targeting, drug encapsulation within liposomes offers a modification of the therapeutic effect in terms of intensity and duration, together with a minimization of undesired side effects. For this purpose, liposomes have to circulate for as long as possible in the vascular system and remain unrecognized by phagocytic cells.

The antimycotic amphotericine is encapsulated in liposomes and marketed as AmBisome to treat severe systemic mycosis. The liposomal encapsulation reduces the toxicity of amphotericine while increasing half-life of the drug and plasma level peaks (43). Due to stability reasons, the parenteral formulation is a lyophilized powder, which has to be reconstituted by adding the solvent just before administration.

The cytostatic daunorubine, which is administered in the later state of Kaposi sarcoma of AIDS patients, is encapsulated in liposomes of about 45 nm size (43). The liposome dispersion is marketed as a sterile, pyrogen-free concentrate (DaunoXome) and has to be diluted with a 5% glucose solution just before being administered as an infusion. Although daunorubicine by itself is cardiotoxic, the liposomal formulation attacks cardiac tissue only insignificantly, but strongly affects the tumor cells by being taken up preferably. It is postulated that small unilamellar vesicles (SUV) may pass through endothelial gaps in recently formed capillaries of the tumor, thereby entering the tumor tissue. At this site, the drug is released from the liposomal carrier and inhibits the proliferation of the tumor cells.

Liposome dispersions for an installation into the lung

A liposomal formulation consisting of a surfactant, which usually coats the mucosa of the bronchi and prevents a collapse of the alveolar vesicles of the lung, has been developed for patients who suffer either from infant

respiratory distress syndrome (IRDS) or adult/acquired respiratory distress syndrome (ARDS). IRDS often affects prematurely born babies who have not yet developed a functional lung surfactant and therefore develop a failure in pulmonary gas exchange. ARDS is also a life-threatening failure/loss of the lung function, usually acquired by illness or accident. Clinical trials with liposomal surfactant have proven to be efficient in prophylactic treatment of IRDS and ARDS.

The surfactant is obtained by extraction from the lungs of cattle, by washing and centrifuging several times. This raw extract is treated with appropriate organic solvents, sterilized by filtration, dried by solvent evaporation under aseptic conditions, resuspended in water, and finally homogenized in a French press under cooling. Care has to be taken to maintain sterility of the extract during all procedures. Special attention has to be paid to transmissible spongiform encephalopathies (TSE). The whole manufacturing process has been validated in terms of a decrease of infectious material by a factor of 10^{21} , although a factor of 10^8 is sufficient. The result is a formulation (Alvefact) that is considered safe in context of TSE and viruses, and it also contains all relevant components of a lung surfactant in terms of pulmonary exchange of gas (43).

Transdermal Patches

To obtain a systemic effect via percutaneous penetration of a drug compound, a high permeability through the stratum corneum and the living tissue beneath is required as well as a high potency of the drug for a low dose to be administered. For an additional short biological half-life, the development of controlled release transdermal systems is a good choice.

Transdermal patches are high-tech devices, which contain the drug substance in a reservoir from which the drug is released in a controlled manner (i.e. zero-order kinetics). The control element is either a membrane or a matrix. Membrane-controlled patches were the first to be marketed. A major disadvantage of these is the so-called dose dumping that occurs in case of a membrane damage during handling. To ensure the desired drug control, even liquid crystalline polymers have been examined with regard to their usefulness in membrane-controlled transdermal patches (46). The matrix-controlled transdermal patch consists of only one functional element, the porous polymer matrix, which not only controls drug release but simultaneously acts as a drug reservoir and adhesive element.

Transdermal patches are marketed worldwide with the drug substances glycerole trinitrate, estradiol,

testosterone, clonidine, scopolamine, fentanyl and nicotine, respectively. The patch has to remain for up to one week at the appropriate body site. In this case the drug amount in the reservoir is rather high. As liquid crystalline vehicles with lamellar microstructure have high solubilization capacities, they are recommended as reservoirs for transdermal patches (47), although the high surfactant concentration of the lamellar liquid crystal might have a irritate the skin. Especially in terms of the membrane-controlled patch, the liquid crystalline vehicle is not in direct contact with the skin and thus will not exhibit an irritating effect on the skin.

Sustained Drug Release from Solid, Semisolid, and Liquid Formulations

The therapy of a chronic disease requires a repeated dosing of a drug. Drugs having a short biological half-life have to be administered up to several times daily within short intervals. To reduce the application frequency, sustained formulations have been developed. Liquid crystalline excipients are appropriate candidates for this because in a liquid crystalline vehicle the drug diffusion is reduced by a factor of 10 to 1000 in comparison with a liquid vehicle such as a solution (48–50). The factor depends on the kind of liquid crystal being employed.

Solid formulations

Solid formulations for sustained drug release may contain mesogenic polymers as excipients. The mesogenic

polymers form a matrix, which is usually compressed into tablets. Some of the most frequently used excipients for sustained release matrices include cellulose derivatives, which behave like lyotropic liquid crystals when they are gradually dissolved in aqueous media. Cellulose derivatives such as hydroxy-propyl cellulose or hydroxy-propylmethyl cellulose form gel-like lyotropic mesophases in contact with water (51), through which diffusion takes place relatively slowly. Increasing dilution of the mesophase with water transforms the mesophase to a highly viscous slime and then to a colloidal polymer solution.

Semisolid formulations

The solubilization of a drug substance in monophasic liquid crystalline vehicles results in semisolid formulations, which are preferably used for topical application. (See the sections on Surfactant Gels and Transdermal Patches.)

Liquid formulations

Sustained release from disperse systems such as emulsions and suspensions can be achieved by the adsorption of appropriate mesogenic molecules at the interface. The drug substance which either forms the inner phase or is included in the dispersed phase cannot pass the liquid crystals at the interface easily and thus diffuses slowly into the continuous phase and from there further into the organism via the site of application. Such as sustained drug release is especially pronounced in the case of multilamellar liquid crystals at the interface.

Fig. 15 Application induced transformation of a reverse micellar solution into a liquid crystal on contact with aqueous media. (From Ref. 10.)

A further possibility is the formation of liquid crystals on contact with body fluids at the site of application. The applied drug solution interacts with body fluids such as plasma, tear, fluid, or skin lipids and undergoes a phase transition to a mono- or multiphasic system of liquid crystals (Fig. 15). For example oily solutions of reverse micellar solutions of phospholipids, which solubilize any additional drug, transform into liquid crystalline lamellar phases by the absorption of water when applied to the mucosa. Drug release is controlled by the liquid crystals because diffusion within the liquid crystalline phase is slowest and thus rate-controlling (50). This principle can be used for ophthalmological administration as well as for nasal, buccal, rectal, vaginal, or even parenteral subcutaneous application (52). However, the peroral administration of such reverse micellar solutions either directly or encapsulated within soft gelatin capsules is not recommended (53) because the sustained release effect is limited by interindividual variations in digestion, such as the amount and composition of the gastric fluid as well as its ability to emulsify and solubilize in terms of enteral absorption.

For the treatment of paradontitis of infected gum pockets, the chemotherapeutic metronidazol has proven to be effective. The crystalline prodrug metronidazolbenzoate, which has to provide the active metronidazol through dissolution and hydrolysis, is suspended in an oleogel (Elyzol Dentalgel). The oleogel consists of glycerol monooleate and sesame oil, which are immobilized within the matrix structure of the surfactant. The base melts at body temperature and spreads evenly over the inner surface of the gum pockets. The molten system absorbs water and transforms into a reverse hexagonal phase. This liquid crystalline structure has a high viscosity. The resulting system adheres well to the surface of the mucosa and releases the active ingredient slowly (10).

Liquid Crystals in Cosmetics

Liquid crystals are mainly used for decorative purposes in cosmetics. Cholesteric liquid crystals are particularly suitable due to their iridescent color effects, and find applications as coloring for nail varnishes, eye shadows, and lipsticks. The structure of these thermotropic liquid crystals changes with body temperature, resulting in the required color effect. In recent times, such thermotropic cholesteric liquid crystals have also been included in body care cosmetics, where they are dispersed in a hydrogel. Depending on whether this dispersion in the hydrogel involves stirring or a special spraying process, the

iridescent liquid crystalline particles are distributed statistically in the gel (Estée Lauder Time Zone Moisture Recharging Complex) or concentrated locally (Vichy Restructure Contour des Yeux) to give the formulation the required appearance. Tests of the cosmetic efficiency of the liquid crystalline constituents have not yet been published.

DOSING OF DRUGS: DOSAGE REGIMENS AND DOSE-RESPONSE

Chyung S. Cook

Aziz S. Karim

Pharmacia Corporation, Skokie, Illinois, U.S.A.

INTRODUCTION

Drugs are administered for their pharmacological effects. In some cases, however, drug therapy includes the risk of undesirable side effects, with each drug having inherently different risks associated with its use. Therefore, it is the objective of physicians to administer a drug with an optimal dosing regimen by selecting the appropriate dosage, route, and frequency of administration to achieve maximal pharmacological efficacy with minimal side effects.

In most clinical situations, drugs are administered either repetitively, at time intervals, or as a continuous infusion to maintain a certain blood concentration at steady state within the known therapeutic concentration range for a given drug. A loading dose may be desirable in order to achieve the target concentration rapidly at the onset of therapy for a drug with a long half-life. These maintenance and loading doses as well as dosing frequency can be determined using pharmacokinetic principles.

DETERMINATION OF DOSE

Maintenance Dose

The general principle that is used to select the appropriate maintenance dose and dosing interval for the average patient is as follows: to maintain a target concentration at the steady state, the rate of drug administration should be equal to the rate of elimination. This can be expressed by the following equation (Eq. 1) using the clearance concept:

$$\text{Dosing rate} = (CLF) \times C_{ss} \quad (1)$$

where CL is clearance, C_{ss} is the steady state concentration of drug, and F is the fraction of the dose that is systemically available. Therefore, if CL , F , and C_{ss} are known, then the appropriate dose and dosing interval can be calculated.

For example, for theophylline, the clearance value is 0.65 mL/min/kg (2.34 L/h for a 60 kg man), the half-life in

healthy nonsmoking asthmatics is approximately 9 h and the effective plasma concentration range is 5–15 mg/L. Because the dose is an IV infusion, the systemic availability, F is 1. If the target plasma concentration at the steady state is 10 mg/L, then the

$$\begin{aligned} \text{IV infusion rate for a 60 Kg man} \\ &= 2.34 \text{ L/h} \times 10 \text{ mg/L} \\ &= 23.4 \text{ mgh.} \end{aligned}$$

If the dose is administered not as an infusion but as a bolus dose (e.g., IV injection or an oral dose), high fluctuations in plasma concentrations between peak (C_{max}) and trough values (C_{min}) will occur. If absorption and distribution are very rapid, fluctuation of plasma concentrations between C_{max} and C_{min} values will be controlled almost entirely by the elimination of the half-life. When the dosing interval is the same as the half-life, the ratio of C_{max}/C_{min} is 2, which is usually tolerable as long as pharmacological activity is directly correlated with plasma concentrations.

Using theophylline as an example again, if the targeted average plasma concentration is 10 mg/L, the dose calculated in the above example is 23.4 mg/h. Therefore, to maintain this concentration as an average concentration, IV bolus doses can be given at 140 mg every 6 h (qid), 187 mg every 8 h (tid), 280 mg every 12 h (bid), or 560 mg once a day (qd). The average concentration for a noninfusion dose regimen is defined as

$$\text{Average plasma concentration} = \text{AUC}/\tau \quad (2)$$

where AUC is the area under the plasma concentration–time curve and τ is dosing interval.

Although all these dose regimens will give the same target average plasma concentration, both $C_{ss,max}$ and $C_{ss,min}$ values will be markedly different. For a given dose, $C_{ss,max}$ and $C_{ss,min}$ values can be estimated using the following equations (Eqs. 3 and 4). Alternatively, the dose that will give the targeted maximal and minimal concentrations can be estimated using these equations:

$$C_{ss,max} = \frac{F \cdot \text{Dose} \cdot e^{-KT_{max}}}{V_{ss}(1 - e^{-K\tau})} \quad (3)$$

$$C_{ss,max} = \frac{K_a \cdot F \cdot \text{Dose} \cdot e^{-K\tau}}{V_{ss}(K_a - K)(1 - e^{-K\tau})} \quad (4)$$

K is the elimination rate constant (equal to 0.693 divided by the clinically relevant half-life). K_a is the absorption rate constant. T_{max} is the time to reach C_{max} . V_{ss} is the volume of distribution at steady state.

For an IV dose, T_{max} is 0, and the term $e^{-KT_{max}}$ becomes 1 in Eq. 3. The term $K_a/K_a - K$ in Eq. 4 also becomes 1. The term $e^{-K\tau}$ is the fraction of the last dose that remains in the body at the end of a dosing interval.

For theophylline (V_{ss} for 60 kg man = 30 L, $K = 0.077 \text{ h}^{-1}$, and $\tau = 6, 8, 12$, or 24 h), the calculated C_{max} , C_{min} and C_{max}/C_{min} values for IV doses are as follows:

Dose regimen	C_{max} (mg/L)	C_{min} (mg/L)	C_{max}/C_{min}
140 mg qid	12.6	8.0	1.6
187 mg tid	13.6	7.3	1.9
280 mg bid	15.5	6.1	2.5
560 mg qd	22.2	3.5	6.3

Because theophylline has a relatively narrow therapeutic index, it would be desirable to determine a dose at which the maximal and minimal concentrations at steady state will be within the therapeutic concentration range (5–15 mg/L). Therefore, the 280 mg bid dose regimen is convenient and adequate to achieve C_{max} and C_{min} within the therapeutic range.

As can be seen in the table, the more frequently a drug is given, the smaller the ratio of peak-to-trough plasma concentrations will be. These phenomena are also demonstrated by the computer-simulated plasma concentration-time curves (Fig. 1). If the dosing interval is equal to or smaller than the half-life, then the fluctuation between C_{max} and C_{min} is usually acceptable even for a drug with a narrow therapeutic window. If the dosing interval is greater than the half-life, a large fluctuation is expected, which may not be desirable for drugs with a narrow therapeutic window. However, if the half-life is very short, dosing at every half-life is not practical. Therefore, different formulations (e.g., extended-release or controlled release) are often used. For drugs with a long half-life (greater than 12 h), the dose can be given once or twice a day to maintain appropriate therapeutic levels.

Following multiple oral doses of a drug that obeys bi-exponential kinetics after IV administration (two-compartment model), the estimation of the $C_{ss,max}$ and $C_{ss,min}$

involves a complicated set of exponential constants for absorption and distribution, as shown below.

$$C_{ss,max} = \frac{F \cdot \text{Dose}(K_{21} - \alpha)e^{-\alpha T_{max}}}{V_{ss}(\beta - \alpha)(1 - e^{\alpha\tau})} + \frac{F \cdot \text{Dose}(K_{21} - \beta)e^{-\beta T_{max}}}{V_{ss}(\alpha - \beta)(1 - e^{\beta\tau})} \quad (5)$$

$$C_{ss,min} = \frac{K_a \cdot F \cdot \text{Dose}(K_{21} - \alpha)e^{-\alpha\tau}}{V_{ss}(K_a - \alpha)(\beta - \alpha)(1 - e^{\alpha\tau})} + \frac{K_a \cdot F \cdot \text{Dose}(K_{21} - \beta)e^{-\beta\tau}}{V_{ss}(K_a - \beta)(\alpha - \beta)(1 - e^{\beta\tau})} \quad (6)$$

where α and β are rate constants for distribution and elimination phases, respectively, and K_{21} is the rate constant from tissue to plasma compartment.

As with the one compartment model, T_{max} is 0 for an IV bolus dose or rapid oral absorption, and both terms $e^{-\alpha T_{max}}$ and $e^{-\beta T_{max}}$ become 1 in Eq. 5. Also in Eq. 6, both terms $K_a/(K_a - \alpha)$ and $K_a/(K_a - \beta)$ become 1.

If both the absorption and distribution are very rapid, these terms can be ignored for simplicity, and a maximal steady state concentration can be easily predicted by omitting the $e^{-KT_{max}}$ term in the numerator of the above Eq. 3 even for the two compartment model. Because of this approximation, the predicted maximal concentration from this equation will be greater than that actually observed.

As discussed above, it is possible to design a dose with pharmacokinetic parameters alone. However, in some cases, pharmacodynamic considerations make the selection of the dose regimen deviate from this principle. If pharmacological half-life is substantially different from pharmacokinetic half-life, then pharmacodynamic half-life (instead of pharmacokinetic half-life) should be used. For example, aspirin is rapidly hydrolyzed to salicylic acid, but the half-life for antiplatelet activity is in days. Therefore, a small amount of aspirin once a day is a good dose regimen in order to achieve the desired pharmacological response. Another exceptional case is for the drugs that are relatively nontoxic even though the pharmacological activity is directly related to plasma concentrations (i.e., there is a large therapeutic index). In this case, a high dose can be given so that the dosing interval can be much longer than the elimination half-life. The half-life of penicillin G is less than 1 h, but it is given at very large doses every 6 or 12 h.

If absorption is slow, and the apparent absorption half-life is much longer than the elimination half-life, then the dose regimen can be based on the apparent half-life of the absorption phase. Changing the formulation is a relatively

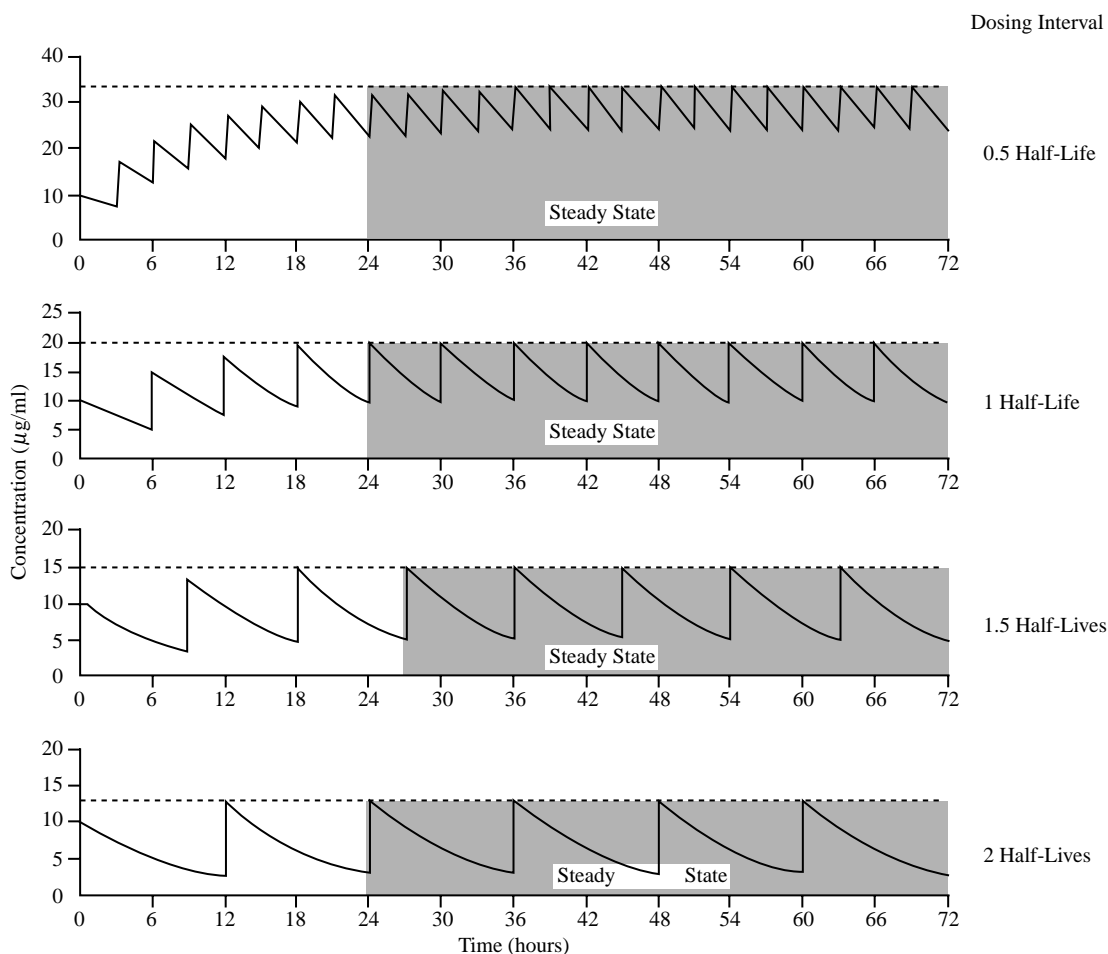

Fig. 1 Simulated plasma concentration-time curves obtained after repetitive doses were given at the intervals of every 1, 1.5, 2, and 3 half-lives. Steady-state levels were obtained between 4 (24 h) and 5 (30 h) half-lives, regardless of dosing interval. The accumulation factors (R) are 3.4, 2, 1.6, and 1.3 for dosing intervals of 0.5, 1, 1.5, and 2 half-lives, respectively.

common approach that is taken for short-acting drugs to extend the duration of absorption. The elimination half-life of nitroglycerin is approximately 2 min. However, nitroglycerin from a transdermal formulation is slowly released, and therapeutic plasma concentrations can be maintained for 24 h.

Another question regarding dose regimen is how often the dosage has to be changed and by how much. This can be usually determined using simple pharmacokinetic principles. The dose will not change by more than 50% and no more often than every 3 to 4 half-lives. Regardless of the half-life and frequency of dosing, it will take 3 half-lives to reach 87.5% of the steady state plasma concentration if the elimination rate constant is smaller than the absorption rate constant (Fig. 2). However, if the elimination rate constant is much greater than the absorption rate constant, the time to reach steady state

will depend on the absorption rate constant and not on the elimination constant.

Loading Dose

The appropriate magnitude for the loading dose can be calculated as follows:

$$\text{Loading dose} = \text{Target plasma concentration} \times V_{ss}/F \quad (7)$$

To achieve steady-state plasma concentrations, it takes approximately 4 elimination half-lives. If the half-life is long and the drug effects are immediately required for treatment of a life-threatening condition, then single or multiple loading doses are sometimes inevitable. For example, the half-life of lidocaine is greater than 1 h.

Fig. 2 Computer-simulated plasma concentration-time curves that show effects of absorption rate on the time to reach steady-state plasma concentrations. When absorption rate is higher than the elimination rate, the time to reach steady-state concentration is dependent on the elimination rate (top three figures). When absorption rate is lower than elimination rate, the time to reach steady-state concentration is dependent on the absorption rate (bottom figure).

However, a patient with arrhythmia after a myocardial infarction cannot wait 4–6 h to achieve therapeutic concentrations of the drug by IV infusion. Thus, the use of a loading dose of lidocaine in the coronary unit is a standard therapy.

For oral doses, the loading dose is usually twice that of the single dose. This is based on the pharmacokinetic principle that the accumulation factor is two when a drug is administered at every half-life. However, a loading dose should be cautiously used, particularly for those drugs with a narrow therapeutic window, because the sensitive individual may be exposed to toxic concentrations. Furthermore, for drugs with long half-lives, it

will take a long time to eliminate a large loading dose from the body.

DOSE- (OR CONCENTRATION-)RESPONSE RELATIONSHIP

A drug is primarily carried by the blood from the absorption site to the target organ/tissue or blood component where the drug interacts with a receptor to produce its effect. Consequently, for many drugs, various types of relationships exist between the plasma or serum

concentration of a drug and its clinical efficacy and toxicity. Much effort has been directed toward establishing reliable mathematical relationships between drug bioavailability input (plasma concentrations) and pharmacological output (response) (1–3). Although the relationship is far from being completely understood, this dose-response relationship is very important in therapeutic decisions, and optimal dosage regimens can be deliberately planned for many drug therapies using the plasma concentration as a reasonable marker, particularly when pharmacological effects are easily measurable (e.g., blood pressure). This dose-response relationship generally depends on whether the plasma concentration is directly or indirectly related to response and whether a drug interacts with its receptor in a reversible or irreversible manner. If there is no apparent correlation between plasma/serum concentrations and the pharmacological effects and/or the effects are not easily measurable, the trial-and-error approach may be more practical.

Directly Reversible Pharmacological Response

The concept of a direct and rapidly reversible pharmacological response implies that the intensity of response is directly associated with the drug concentration at the site of action. In this category, two models (pharmacodynamic and pharmacokinetic–pharmacodynamic) are discussed.

In the pharmacodynamic model, the drug concentration at the receptor site is proportional to the drug concentration in the plasma, regardless of the pharmacokinetic model (one compartment or multicompartment), and the interaction between the drug and receptor is directly and rapidly reversible after drug administration.

Plasma concentration (C) and intensity (I) of the pharmacological response often follow an empirical relationship, known as the Hill equation:

$$I = \frac{I_{\max} C^n}{(C_{50}^n + C^n)} \quad (8)$$

where I_{\max} is the maximal effect attributable to the drug and C_{50} is the concentration producing 50% of the maximum effect. Two examples of this are the *in vivo* effect of *d*-tubocurarine on muscle strength in patients and the plasma concentration–antiarrhythmic effect of tocainide in humans.

Another common and empirical relationship between concentration and response is the sigmoidal plot of response vs. logarithm of dose, plasma concentration, or drug concentration in the body. Very often, this curve shows excellent linearity from at least 20–80% of the maximum attainable intensity of response, which is a

region of particular interest in drug therapy. Such apparent linearity between response and log plasma concentration has been demonstrated for a number of drugs, such as theophylline and propranolol. Relating response to the logarithm of plasma concentration rather than to the logarithm of dose reduces the variability in response due to differences in absorption, metabolism, and excretion among patients.

The pharmacokinetic–pharmacodynamic model is one in which drug concentrations at the effect site are not known or cannot be estimated without knowledge of the drug effect. If the pharmacological response is associated with a peripheral compartment (not with a central compartment) that receives a substantial mass of drug, a linear, log-linear, or sigmoidal relationship may also be obtained when the response is plotted against the calculated concentrations of the drug in the peripheral compartment (not plasma concentrations). A linear relationship was obtained between behavior response and the predicted concentration of the drug in the tissue compartment after IV administration of *d*-lysergic acid diethylamide (LSD) to humans.

Indirect Pharmacological Response

In contrast to the direct pharmacological responses discussed above, some pharmacological responses are indirect and represent the net result of several processes of which only one is influenced by the drug. In this case, a direct relationship between plasma concentration and pharmacological response may not be obtained. However, if the process influenced by the drug can be identified, then the drug concentration may relate to changes in this process. This concept is illustrated by the effects of oral anticoagulants such as warfarin.

Warfarin inhibits the synthesis of certain vitamin K-dependent clotting factors. However, warfarin has no effect on the physiological degradation of these factors. Therefore, the pharmacological response of warfarin should be based on the inhibitory effect on the synthesis of the clotting factor (prothrombin) rather than on the change in clotting time. These mechanism-based models were found to be relevant for the clinical effects of numerous drugs (4). Many metabolic and endocrine systems provide similar modeling strategies (5).

Irreversible Pharmacological Response

Most drugs produce a reversible pharmacological response. However, some antibiotics, irreversible enzyme inhibitors, and anticancer agents incorporate irreversibly or

covalently into a cell's metabolic pathway. This results in an irreversible effect—cell death. Complex kinetic models are used to explain the relationship of dose-chemotherapeutic effects for some drugs, such as methotrexate, cyclophosphamide, and arabinosylcytosine (2).

FACTORS AFFECTING DRUG RESPONSE

Dosage regimens are generally derived using average pharmacokinetic parameters to maintain plasma concentrations of the drug within the therapeutic window. For many drugs, both therapeutic range and toxic concentrations have been established (6). However, for a fixed dose, the plasma concentration of a drug within a patient can be influenced by many pharmacodynamic and pharmacokinetic factors. Therefore, these factors must also be taken into consideration for maintaining desired therapeutic concentrations of a drug.

Pharmacokinetic Factors

Factors affecting absorption

Factors affecting drug absorption include formulation, disease state, food effect, and drug–drug interaction. Formulations used for oral administration include solutions, suspensions, capsules, and uncoated and coated tablets. Depending on the formulation of a drug, the absorption characteristics may differ substantially. Slow-release oral formulations are often used to prolong the drug's activity and to reduce the fluctuation between C_{\max} and C_{\min} values.

Intestinal surgery and disease states have been shown to alter the absorption of some drugs, although information on this subject is limited. For a given disease state or surgery, drug absorption may be increased, unchanged, or decreased, depending on the drug. Therefore, the effect of a particular disease condition on drug absorption cannot usually be predicted from the existing information.

The effect of food on the absorption of a drug from the gastrointestinal (GI) tract is quite variable and depends on the physicochemical properties of the drug substance and the mechanism by which it is absorbed. The presence of solid food in the stomach will tend to decrease the rate of stomach emptying and thus delay the absorption of the drug, which often results in decreased systemic availability of the drug. The relative bioavailability of lincomycin is reduced to about 60% when given 1 h before breakfast and to about 20% when given immediately after breakfast, compared with that observed

after oral administration to fasting subjects. A potentially dangerous situation may arise owing to delayed absorption of hypnotic agents in nonfasting patients. With the hypnotic capuride, a 42-min difference in onset of absorption has been observed between fasting and nonfasting subjects.

The presence of food is also found to increase gastrointestinal motility and splanchnic blood flow up to 30%. Consequently, the absorption of some drugs is either unaffected or increased by food. Among the beta-blocking agents, absorption of bevantolol and oxprenolol was unchanged with food, whereas absorption of metoprolol, labetalol, and propranolol was increased, but the absorption of atenolol and sotalol was decreased. The oral absorption in humans of the antifungal antibiotic griseofulvin is substantially greater with food of high fat content than without food. Because a high fat concentration in the small intestine stimulates bile secretion, absorption of the relatively lipophilic drug may be increased by enhancing its dissolution in the GI tract. Furthermore, the increase in splanchnic blood flow resulting from food consumption may contribute to the enhanced absorption. However, relatively polar and poorly permeable drugs show a tendency toward reduced absorption in the presence of food (7). Food decreases absorption of alendronate, astemizole, captopril, didanosine, and penicillamine.

Food effects on drug absorption will depend not only on the physical and chemical properties of the drug substance but also on the formulation. Following oral administration of theophylline, the absorption rate of the drug can be either increased or decreased with food, depending on the formulation (8). Generally, the greatest food effect is observed when the drug is taken immediately after a meal; the degree of interaction decreases as the time between eating and drug-dosing increases (9). Extensive reviews of the effect of food on drug absorption can be found in the literature (10–12).

Drug interaction is another important factor affecting absorption. In general, interactions that interfere with absorption either involve binding or chelation of drugs in the GI tract, rendering them nonabsorbable, or involve effects on gastric emptying or gastrointestinal motility. In addition, gastric pH changes may affect on the absorption of some drugs.

Antacids, particularly aluminum hydroxide gel, reduce the absorption of most tetracycline drugs by forming an insoluble complex in the gut. Simultaneous administration of iron (ferrous sulfate) with tetracycline, oxytetracycline, methacycline, or doxycycline seriously impairs the absorption of these antibiotics. Adsorbants such as kaolin (an antidiarrheal agent) substantially reduce the absorption of lincomycin and promazine. Ion-exchange resins, such as

cholestyramine, strongly bind many anionic and neutral drugs in the GI tract and interfere with the absorption of anticoagulants and thyroxine. Imipramine significantly reduces bioavailability of levodopa in humans, presumably because delayed absorption by reducing gastric emptying time enhances metabolism of levodopa in the gut. Orally administered ketoconazole requires an acidic medium to dissolve adequately and, therefore, antacids, anticholinergic drugs, H₂ blockers, or acid pump inhibitors (e.g., omeprazole) will reduce the bioavailability of this drug. Metoclopramide, cisapride, and cathartics increase GI motility and may decrease the absorption of drugs that require prolonged contact with the absorbing surface and those that are absorbed only at a particular site along the GI tract. Anticholinergics decrease GI motility and may increase absorption by prolonging contact with the area of optimal absorption or may reduce absorption by slowing dissolution and gastric emptying. The interactions between drugs have been reviewed in detail (13–15).

Factors affecting distribution

After entering the general circulation, a drug is carried throughout the body and is distributed to various tissues. The drug distribution depends on the relative affinity of binding to plasma protein, red blood cells, and tissues. However, it can be altered in the presence of other drugs, in some disease states, and due to the age of the patient.

The risk of interactions resulting from the displacement of the drug from proteins is significant, primarily with drugs that are highly protein-bound (>90%) and that have a small apparent volume of distribution and a relatively narrow therapeutic window. This can result in a high concentration of unbound drug temporally (the first few days), which may have clinically important effects. Trichloroacetic acid, a major metabolite of chloral hydrate, displaces warfarin from its binding sites on plasma albumin. This displacement temporarily elevates plasma levels of warfarin and, thereby, increases the pharmacological effect per unit dose. Administration of 1 g of chloral hydrate daily for 1 week to subjects on warfarin increases the hypothermic effect by 40–80%. When valproic acid and phenytoin are coadministered, unbound phenytoin concentrations increase significantly in some patients causing more adverse reactions, even when total phenytoin serum concentrations are within the usual therapeutic range.

Disease states are another factor that may affect the binding of drugs to proteins in plasma and other tissues. Unusually low binding of drugs to plasma proteins has been observed in various diseases. For example, the percentage of unbound phenytoin in plasma was 5.8–7.3% in normal subjects, whereas the percentages of unbound drug in patients with renal diseases (azotemia

or uremia) were 8–25%. In addition to renal diseases, liver diseases, hyperbilirubinemia, and hyperlipidemia are reported to lower plasma protein binding of some drugs. However, during physiological stress (e.g., myocardial infarction, surgery, ulcerative colitis, and Crohn's disease), the plasma protein binding of basic drugs (e.g., propranolol, quinidine, and disopyramide) increases, and volume of distribution decreases accordingly due to the increase in concentrations of the α 1-acid glycoprotein.

Age-related changes in drug distribution have been reported. The apparent volume of distribution is somewhat larger in newborns and infants than in adults. The estimated volume of distribution of sulfamethoxypyridazine in newborns and infants is 0.47 and 0.36 L/kg, respectively, whereas the values are 0.20–0.26 L/kg in children, adults, and elderly subjects. The volume of distribution of chlorthalidone is substantially larger in the elderly (0.52 L/kg) than in the young (0.42 L/kg). The age-related difference in the volume of distribution may be due to a difference in plasma protein binding and/or in the relative size of body compartments.

Factors affecting metabolism

Drug metabolism is a primary mechanism for removal of drugs from the body. Drug metabolism may be affected by age, disease state, polymorphism, and inhibition or induction of drug-metabolizing enzymes. Sex differences in drug metabolism are minor in humans and usually are not clinically important.

Although hepatic drug metabolism is generally slower in neonates as compared with adults, children actually metabolize certain drugs more rapidly than adults. The half-life of theophylline averaged 3.7 h in children but ranged from 5 to 9 h in nonsmoking adults. Children also metabolize antipyrine, clindamycin, diazoxide, and phenobarbital more rapidly than adults. In elderly subjects, metabolism of some drugs (e.g., amobarbital, antipyrine, phenylbutazone, and chlorthalidone) has been reported to be less efficient than in younger subjects. Thus, the aging process may reduce the total clearance of a drug and extend its elimination half-life. After oral administration of amobarbital, the mean percentages of the dose excreted as the hydroxy metabolite in 0–24 h urine specimens was reduced from 14% in the younger subjects (20–40 years of age) to only 4% in the elderly subjects (>65 years of age). The apparent elimination half-life of chlorthalidone showed a strong correlation with age, increasing from a mean of 9.5 h in the young to 37 h in the elderly. Consequently, the plasma concentrations of these drugs were greater in the elderly subjects than in the younger subjects.

Genetic polymorphism in metabolism is a very important factor in the variability in drug elimination. The metabolism of isoniazid (and other drugs that have a hydrazine moiety such as sulfamethazine, sulfapyridine, hydralazine, procainamide, and dapsone) is more rapid in some individuals than in others. The major route of elimination of isoniazid in humans is via metabolism to acetylisoniazid by hepatic *N*-Acetyltransferase; thus, the half-life of the drug depends on how rapidly the drug can be acetylated. In about 50% of the U.S. population and in 5–10% of the Asian population, hepatic *N*-acetylation is slow. In those with extensive (rapid) metabolism, the half-life of the drug is 45–80 min, whereas in those poor (slow) metabolism, the half-life is 140–200 min. Slow acetylators require a longer time to acetylate these drugs and, therefore, are more susceptible to adverse effects caused by the parent compound (e.g., peripheral neuritis with isoniazid, lupus erythematosus with hydralazine or procainamide, and sedation and nausea with phenelzine). Compared with slow acetylators, the rapid acetylators require larger and more frequent doses of such a drug in order to obtain the desired therapeutic response.

Drugs that are metabolized by the cytochrome P-450 (CYP) isoenzymes CYP2D6, CYP2C9, and CYP2C19 also exhibit genetic polymorphisms. An example of CYP2D6 metabolism is debrisoquine. In about 5–10% of Caucasians in North America and Europe and about 1% of Asians, 4-hydroxylation of debrisoquine is reduced, and such individuals are at increased risk for toxicity (orthostatic hypotension). Beta blockers (metoprolol and timolol), antiarrhythmic drugs (encainide and flecainide), tricyclic antidepressants (amitriptyline, nortriptyline, and desipramine) and an antitussive drug (dextromethorphan) are also metabolized by CYP2D6. Therefore, in the CYP2D6 poor metabolizers, unusually large therapeutic responses and/or more adverse effects may be observed compared to extensive metabolizers.

Phenytoin is metabolized by CYP2C9. In CYP2C9 poor metabolizers, increased toxicity (e.g., excessive CNS depression) was observed. *S*-mephenytoin is stereoselectively metabolized by CYP2C19. About 3–5% of Caucasians in North America and 20% of Asians metabolize mephenytoin slowly, which increases their risk of a major side effect (transient sedation). In such persons, other drugs metabolized by the same isoenzyme as mephenytoin will also be poorly metabolized, and pharmacological activity and/or side effects of these drugs may be increased. These drugs include mephobarbital (an anticonvulsant), proguanil (antimalarial), and possibly diazepam (an anxiolytic). These drugs have a substantially longer half-life in poor metabolizers than in extensive

metabolizers. Thus, caution must be used for the patient with limited capacity of metabolism.

Other genetic polymorphisms include deficiencies in aldehyde dehydrogenase-2 (an enzyme involved in ethanol metabolism), alcohol dehydrogenase (another enzyme involved in ethanol metabolism), glucose-6-phosphate dehydrogenase (G6PD), or glutathione synthetase. Patients with G6PD deficiency (about 10% of Black males) are at increased risk of developing hemolytic anemia when given oxidant drugs, such as antimalarials (e.g., chloroquine, pamaquine, and primaquine), aspirin, probenecid, and vitamin K. Patients with low levels of glutathione synthetase in hepatocytes are at increased risk of liver damage if given drugs metabolized by glutathione conjugation, such as acetaminophen and nitrofurantoin.

Some disease states may have clinically significant effects on drug metabolism. If hepatic metabolism is an important route of drug elimination, any dysfunction of the liver may lead to a change in the pharmacokinetics of that drug, and subsequently plasma concentrations of the drug will be different from those in a patient with normal liver function. The clinical significance of the changes in drug elimination depends on the type or severity of the disease. Antipyrine has often been used as a model drug for the investigation of the effects of liver disease on oxidative drug metabolism in humans. In healthy subjects, the average half-life of antipyrine is approximately 12 h. In contrast, the half-life of the drug in patients with liver cirrhosis or chronic active hepatitis averages 34 and 26 h, respectively. However, the half-life of antipyrine does not provide a quantitative index of the degree of impairment of drug elimination in a patient for a specific drug. Some other examples of drugs whose half-lives in patients change due to impairment of metabolism in particular disease states include hexobarbital in hepatitis, meperidine in liver cirrhosis, propranolol in chronic liver diseases, and rifampin in obstructive jaundice.

Enzyme induction or inhibition is another factor that alters the rate of metabolism of many drugs. Many drugs, polycyclic hydrocarbons, insecticides, and other environmental chemicals (e.g., cigarette smoke) stimulate activity of microsomal enzymes in the liver. Consequently, repetitive administration of certain drugs or continuous systemic exposures to certain chemicals may facilitate elimination of other drugs by increasing their metabolism. Phenobarbital and other barbiturates are among the most potent and widely studied inducing agents in humans. During repetitive administration of phenobarbital (2 mg/kg/day) for a period of 4 weeks, a substantial decrease in the efficacy of warfarin was observed after the first week, as shown by a substantial decrease in mean prothrombin time. Rifampin also induces metabolism of

warfarin. After administration of 600 mg of rifampin a day to subjects receiving repetitive daily doses of warfarin, plasma concentrations of warfarin were reduced to near nondetectable levels.

Some drugs, such as rifampin, induce their own metabolism. During repetitive administration of rifampin at a daily dose of 600 mg for 30 days, the elimination half-lives of rifampin were 4.2 and 1.9 h on the first and last days, respectively. Carbamazepine also shows pronounced self-induction. The plasma concentrations at steady state predicted from single-dose data were two to three times higher than the actual concentrations observed during chronic treatment.

Whereas the clinical consequence of enzyme induction is usually a decrease in the efficacy of the drug, inhibition of drug metabolism can lead to serious adverse effects from the accumulation of drugs to toxic concentrations. However, by identifying the CYP isozymes responsible for metabolism of substrates and inhibitors and determining their *in vitro* inhibition constants, it is possible to predict clinically significant drug interaction in many cases. Chloramphenicol is a potent inhibitor of the metabolism of CYP2C9 substrates (e.g., tolbutamide, phenytoin, and dicumarol) in humans. Treatment with 2 g of chloramphenicol for several days resulted in a marked rise in the steady state serum concentrations of tolbutamide and phenytoin. The area under the plasma concentration-time curves of tolbutamide was elevated five-fold by coadministration of sulfaphenazole.

Among the CYP isozymes, CYP3A4 is responsible for the metabolism of the widest range of drugs and endogenous compounds in humans. It accounts for 60% of CYP isoforms in human liver. Therefore, if a drug is metabolized by CYP3A4, concomitant administration of other drug that is metabolized also by CYP3A4 may result in a drug interaction. For example, ketoconazole inhibited metabolism of the nonsedating antihistamines terfenadine and astemizole, and cisapride. As a result of CYP3A4 inhibition, life-threatening arrhythmic side effects of these drugs occurred. An extensive review of clinically significant drug interactions can be found in the literature (16).

Factors affecting excretion

Renal excretion of drugs is accomplished by both a pH-dependent diffusion and active secretion. Changes in urine pH may occur due to disease states, dietary factors, or simultaneous administration of drugs. The effect of urinary pH change on the elimination rate of acidic and basic drugs can be pronounced and may be predicted according to the pH partition hypothesis as long as excretion of the drug in urine is an important route of elimination.

For an acidic drug, a more alkaline urine increases ionized drug concentration and decreases reabsorption at the distal tubule. Consequently, elimination of the drug will be faster. On the other hand, more acidic urine leads to a decreased concentration of the ionized acidic drug, resulting in increased reabsorption and slower elimination. After sulfaethidole was administered to humans, the half-life decreased from 11.4 to 4.2 h when urinary pH increased from 5 to 8, respectively. The elimination rates of sulfalene and sulfasymazine were doubled by the administration of sodium carbonate, which increased urine pH from 6 to 8. Elimination of salicylate was slower in humans with low urine pH, and higher plasma concentrations were achieved.

For basic drugs, urinary excretion increases with low urinary pH and decreases with high pH. As a result, patients receiving amphetamines or closely related drugs may be placed at risk by relatively small changes in urine pH. Patients with alkaline urine had intense psychoses lasting more than 3 days after the last dose of amphetamine.

Age-related alteration of renal function is a very important factor in selecting the dose regimen. Renal function in newborns is incompletely developed. Neonatal renal plasma flow and glomerular filtration rates (normalized for body surface) are only 30–40% of those of adults. The half-life of penicillin G is 3.2 h in newborns (up to 6 days of age) and 1.4 h in infants (14 days of age or older), whereas in older children and adults, it is about 0.5 h. The mean half-life of gentamicin is about 5 h in newborns under 1 week of age and about 3 h in infants 1–4 weeks of age. The half-life of gentamicin in older infants and adults is approximately 2 h. Thus, drugs that depend on renal excretion as the principal mode of elimination would be expected to have a longer residence time in infants.

Impaired renal function may affect drug elimination to varying degrees, depending on the extent of the contribution of renal clearance to the total clearance. The greater the contribution of the renal clearance to the total clearance, the greater the influence of renal disease will be on drug elimination and steady state concentration in the plasma during repetitive dose administration.

Pharmacodynamic Factors

There are many examples of drugs that interact at a common receptor site or that have additive or inhibitory effects. Also, there are some other interactions of an apparently pharmacodynamic nature whose mechanism is poorly understood.

Monoamine oxidase (MAO) inhibitors, such as, phenelzine or tranylcypromine, cause norepinephrine to accumulate within adrenergic neurons. Thus, drugs that release norepinephrine (e.g., indirectly acting sympathomimetic amines, amphetamine, and phenylpropanolamine) can produce an exaggerated response including severe headache, hypertension, and cardiac arrhythmias. MAO inhibitors are present in many over-the-counter drugs for cold, allergy, and diet products, and patients taking MAO inhibitors should avoid such products.

OPTIMIZATION OF DOSAGE REGIMENS FOR INDIVIDUAL PATIENT

Dose regimen is determined using the average pharmacokinetic parameters. However, unpredictable variation exists even among normal individuals. For many drugs, one standard deviation in the values observed for F , CL , and V_{ss} is about 20%, 50%, and 30%, respectively. Therefore, 95% of the time, the C_{ss} that is achieved based on average pharmacokinetic parameters will be between 35 and 270% of the target concentration. This is not an acceptable range, especially for the drugs with narrow therapeutic index. If F , CL , and V_{ss} can be directly measured and the dose is further adjusted for body weight or surface area, drug–drug interactions, and disease state, such as renal impairment (for renally excreted drugs), then a more precise dose regimen can be made for a particular patient.

Dosage Adjusted for Body Weight

The same amount of drug in different individuals can result in different drug concentrations in plasma, because the apparent volume of distribution of a drug depends on the size of the body compartment as well as on the relative binding of the drug in the vascular and extravascular spaces. The volume of total body water and extracellular fluid in subjects with a normal lean to fat ratio is directly proportional to body weight. A relationship exists between the apparent volume of distribution and body weight, as well as between steady state plasma concentration and body weight. To maintain the therapeutic plasma concentration at the steady state in nonobese adults, it is better to determine the dose on a mg/kg body weight basis than to administer a fixed dosage per patient.

The distribution of relatively polar drugs (e.g., digoxin and gentamicin) is limited to body water, whereas highly lipid-soluble drugs (e.g., thiopental) distribute into fat. Therefore, for polar drugs, the use of lean body mass instead of total body weight allows for a more predictable

dose–response relationship in obese patients. In fact, if digoxin dosage for obese individuals is calculated on the basis of total body weight, plasma concentrations of the drug may be dangerously high.

The percentages of fat and lean body mass in an individual may be estimated with the help of (Eqs. 9 and 10).

$$\% \text{ Fat} = 90 - 2(H - G) \quad (9)$$

where H is height and G is girth, both in centimeters, using umbilical level at expiration.

$$\text{Lean bodymass} = (100 - \% \text{ fat}) \times \text{weight(in kg)} \quad (10)$$

Dosage adjusted for body surface area

Children require and tolerate a larger mg/kg dose than adults and cannot be considered as small adults. For example, the doses of digoxin required to maintain mean plasma concentrations of about 1–1.5 ng/ml are 15–20 $\mu\text{g/kg}$ per day for children 4 weeks to 2 years of age, 10–15 $\mu\text{g/kg}$ per day for children 2–12 years of age, and 4–5 $\mu\text{g/kg}$ per day for adults. Reasonable estimates of the doses required in children are often obtained by calculating the child's dose on the basis of body surface relative to that of an adult. An estimate of body surface area may be made from Eq. 11.

$$S = (W^{0.425} \times H^{0.725} \times 71.84) / 10^4 \quad (11)$$

where S is surface area in m^2 , W is body weight in kg, and H is height in cm. The approximation of the body surface area for children can be obtained using the simplified (Eq. 12).

$$S = 0.088 W^{0.728} \quad (12)$$

The body surface area of the average adult is usually taken to be 1.73 m^2 .

In general, for the average 3-month-old child weighing 6 kg, the body surface-adjusted dose is 2 times greater than the mg/kg dose given to an average adult, whereas for the average 5-year-old weighing 20 kg, the body surface-adjusted dose is 1.5 times greater than the mg/kg dose. The requirement of larger mg/kg doses in children than in adults may be related in part to the fact that total body water and extracellular fluid make up a higher percentage of the total body weight in children than in adults.

Dosage adjusted for drug interactions

Epidemiological studies demonstrate that if 5 or fewer drugs are coadministered, the rate of drug-related adverse

reactions is approximately 4%. However, when 20 or more drugs are prescribed, the rate of adverse reactions increases to 45%. Therefore, patients should take as few drugs as possible for concurrent use. If more than one drug therapy is required and interactions between the coadministered drugs are known to be clinically significant, the dosage of one or more drugs may be increased or decreased based on the clinical response and severity of side effects in the individual patient, or each drug may be administered with a certain time interval, depending on the situation during the concurrent therapy. After one or more drugs is discontinued, the dosage regimen of the other drug(s) may be readjusted for continuing therapy. If a drug or a particular formulation of a drug is known to have a food effect, the drug or formulation must be given at least 1 h prior to or after food intake for reliable therapy.

Dosage adjusted for renal impairment

The renal clearance of the drug is proportional to endogenous creatinine clearance, irrespective of the mechanisms (i.e., filtration, reabsorption, or secretion), and the creatinine clearance is used as an indicator of the severity of the disease. Furthermore, it is possible to

predict the half-life of a drug in a patient with renal disease based on the creatinine clearance and on a knowledge of the pharmacokinetics of the drug in normal subjects, as illustrated with cefazolin in Fig. 3.

The half-life of some drugs is changed sufficiently in patients with impaired renal function to warrant consideration of a change in the usual dosage regimen, thus preventing toxic accumulation of the drug in the body. Changes in regimen usually take the form of reducing the dose per dosing interval or increasing the length of the dosing interval. Either change is usually roughly proportional to the relative difference in half-life between the patients with and without renal disease. Cephalexin is administered as a 250-mg to 1-g dose every 4–6 h. Its average half-life in patients with normal renal function is about 0.5–1 h. In a patient with a creatinine clearance of 10–15 ml/min, the half-life of the drug increased about eightfold because cephalexin is eliminated almost entirely by urinary excretion of the parent drug. The dosing frequency suggested for this patient is the usual dose every 24 h, which is 3–6 times longer than the usual dosing interval. A comprehensive guide to drug usage in adult patients with impaired renal function is available (17).

Dosage adjustment for other diseases

If the major route of elimination of a drug is by metabolism in the liver and the patient has liver dysfunction, then dosage of the drug or frequency of dosing may be reduced. However, unlike patients with renal dysfunction, the degree of impairment of drug elimination in an individual with liver dysfunction cannot be predicted. In general, little change is necessary in dosage regimens when liver disease is inactive, although doses should be kept low, and particular care should be taken with sedative and antidepressant drugs. When liver disease is present, the dosage regimens of some drugs (e.g., sedatives and analgesics) in each patient should be titrated to his or her clinical response. In selected instances, plasma concentrations of the drug should be monitored and dosage regimens adjusted based on plasma concentration measurements.

It is generally recommended that altered plasma protein binding in the disease state does not require dosage adjustment. However, in patients with hypoalbuminemia, the incidence of drug toxicity appears to be increased, and, thus, dosages should be reduced. Patients showing toxicity may have impaired elimination in addition to altered plasma protein binding. In fact, it has been suggested that low serum albumin concentrations may be a marker for the integrity of liver function.

Fig. 3 Relationship between renal function (expressed by creatinine clearance) and overall elimination rate constant for cefazolin after a single intramuscular injection. (From Ref. 17.)

DRESSINGS IN WOUND MANAGEMENT

Sarah M.E. Cockbill

University of Wales College, Cardiff, United Kingdom

INTRODUCTION

Throughout history, many diverse materials of animal, vegetable, and mineral origin have been used to treat wounds. They range from the hot oils and waxes reported in the Ebers papyrus (1) to the animal membranes and faeces of the Middle Ages to the picked oakum of the 19th century. Moist poultices are described on Sumerian tablets inscribed as early as 2100 B.C. (1, 2). Medieval manuscripts illustrate examples of both *moist environment* and *biological healing*, such as the practice of using dogs to lick wounds, particularly post surgery, to moisten, cleanse, and stimulate healing, thus relying on the now recognised, but at that time unknown, presence of antibacterial agents and growth factors in the saliva (3). Ambroise Paré (1510–1590), the *father* of wound management, used a semi-occlusive, oil-impregnated dressing in the 16th century to obtain “a softness of the tissues” (4). A Diachylon plaster consisting of a mucilagenous, moist mass made from linseed and marshmallow was originally described by Galen (130–201). This could be considered a precursor to our modern hydrogels (4). In 1819, Abraham Rees, in his treatise on the use of lynette, emphasized the need to prevent “scab” formation by keeping the wound edges apart with oil-soaked dossils, which were nonadherent and moisture retaining (5). In the 19th century, wet compresses or cataplasma kaolin were applied to wounds and covered in waterproof fabrics such as jaconet, battiste, or oiled silk to maintain humidity. The 20th century saw the production of leno gauze impregnated with soft paraffin, Tulle Gras.

The literature references to early wound management give detailed descriptions of the wound types but only a cursory description of wound dressing materials. The first authoritative monographs appeared in early London and Edinburgh hospital dispensaries and later in the British Pharmaceutical Codices. The development of wound management products can be traced by examining these Codices together with the *British Pharmacopoeia* (6). The information is reflected in similar publications in the *United States Pharmacopoeia* and other national standards.

Advances in the design and efficacy of wound management products were spasmodic and limited to the adaptation of available materials until 1960. Up to that date, the products were primarily of the *plug and conceal* variety, exemplified by lint, gauze, cotton, wool, and tow, which were considered to be *passive* products that took no part in the healing process. Little or no attention was paid to the functional performance of a product, and minimal consideration was given to the different healing environments required for different wound types.

The new generation of products was a rejection of the traditional passive *cover all* dressing philosophy and was potentiated by advances in knowledge of the humoral and cellular factors associated with the healing process and the realization that a controlled microenvironment is necessary if wound healing is to progress at the optimum level. Such environmental control dressings could be classified as *interactive*.

Both the acellular and cellular activities involved in the healing cascade are optimized by a wound microenvironment that will allow the free movement of cells and effective response to *bioactive* compounds. This optimal response can be expected where environmental factors such as temperature and humidity are at subdermal levels.

PERFORMANCE CRITERIA

The concept of moist wound healing is generally attributed to George Winter after his much cited publication in *Nature* (7), although Bull and his co-workers published results in 1948 (8) showing enhancement of healing under a ‘film’ dressing, but no explanation was given. In 1975, Winter expressed his initial concern with the secondary trauma produced at the wound surface by removing the strongly adhered fibrous and fabric dressings of the 1960s and described his attempts to produce a moist wound environment and, thereby, reduce dressing adherence by using polythene sheets as wound covers (9). This gave an unacceptable *wet* environment that resulted in tissue maceration. An alternative microporous polyvinyl chloride material that Winter reported as having a permeability

to water vapor of “about $2500 \text{ g m}^{-2} 24 \text{ h}$ ” proved more successful.

In 1979, Turner (10, 11) identified the performance criteria for a wound dressing product that would successfully contribute to an acceptable microenvironment. These were:

- to maintain a high humidity at wound/dressing interface
- to remove excess exudate and toxic components
- to allow gaseous exchange
- to provide thermal insulation
- to afford protection from secondary infection
- to be free from particulate or toxic contaminants
- to allow removal without trauma at dressing change

These criteria are still valid and have not been greatly modified. An additional requirement that results from our greater knowledge of the growth factors involved in the healing process is to be compatible with the humoral and cellular factors involved in healing.

Humidity Levels and Removal of Exudate

Partial or full thickness wounds exposed to the air will demonstrate a lower temperature than ambient due to the latent heat lost through tissue fluid evaporation. The clotting process and fibril development produces an occlusive dry eschar or scab that effectively seals and insulates the wound, thereby limiting moisture and gaseous transmission and restricting the migration of epithelial cells to the moist subscab tissue. The result is slow healing with a high contamination and infection risk, together with possible excessive scarring in an excised wound from closure without full cavity granulation.

The maintenance of a high humidity between the wound and the dressing is, therefore, a requirement for rapid epidermal healing. A drying wound will result in a gas-impermeable eschar and will require epithelial cell penetration to a moist lower level, resulting in prolonged healing time.

The absorption of excess exudate not only avoids tissue maceration but also removes exotoxins or cell debris that may retard growth or extend the inflammatory phase of the healing process. The balance between humidity and absorption is critical, and excessive wicking must be avoided to prevent drying and necrosis.

Gaseous Exchange

Gaseous permeability will allow water vapor transmission, which may be particularly important in a high exudate wound such as a burn, sacral, or high exudate leg ulcer. Of equal significance will be the effect of gaseous exchange on oxygen (pO_2) and hydrogen ion (pH) levels; movement

across the dressing of oxygen and carbon dioxide will directly relate to cellular and humoral factor activity. Epithelization of the wound is greatly accelerated by the availability of atmospheric oxygen, which dissolves in the serous exudate to supplement the oxygen transported to the wound area by haemoglobin and which is subsequently directly utilized by the migrating epidermal cells.

Thermal Insulation

Thermal insulation will assist in maintaining the wound temperature at a level as close to body core temperature as possible. Phagocytic and mitotic activity are particularly susceptible to temperatures below 28°C . Thermal insulation and *warm* dressing change conditions are very important if the optimum healing rate is to be maintained. A long exposure of wet wounds may reduce the surface temperature to the point where mitotic activity ceases and the recovery of that tissue may take up to 3 h. Temperatures of 30°C and above may be found beneath a good insulating dressing, and this will result in high mitotic activity with rapid epithelization and improved granulation (12).

Impermeability to Microorganisms

Bacterial impermeability has a dual role. One, the wound will not heal if it is heavily infected, and the inflammatory phase will be extended, and two, unless topical or systemic antibacterial agents are used, a more general infection could result. However, a limited number of microorganisms are tolerated by most wounds, and the destructive or cleansing phase produced by phagocytic activity should result in a self-sterilized environment. The wound should then be protected from secondary infection or, if still contaminated, be prevented from transmitting the infective organisms (Fig. 1).

A dressing should, therefore, be impermeable to airborne microorganisms that may fall on its surface and penetrate to and infect the wound. It should also act as a barrier to any wound organism that may be transmitted to the dressing surface and become airborne, thus causing cross-infection. Organism transmission occurs most frequently in dressings that exhibit *strike through* of the exudate to the wound surface, providing a wet pathway to or from the wound surface. The passage of organisms can take as little as 6 h from the time of *strike through*.

Freedom from Particulate and Toxic Wound Contaminants

Both particles and toxic compounds that may contaminate a wound will be responsible for disrupting the healing

Fig. 1 Wound healing response to a controlled microenvironment.

pattern. The incorporation of fibrous particles into a wound may result in a granuloma, which could subsequently reduce the wound strength and induce keloid scarring. It is well documented that particulate contamination can also reduce the infection resistance levels by a factor of 1.0×10^{-6} . Thus, organism levels that previously would have been self-sterilizable become infective and colonize the wound to produce a gross infection.

Trauma during Dressing Change

The wound environment may be optimally maintained with a product that has the preferred performance parameters but, nevertheless, is disrupted during the dressing change. The hazards of temperature change and secondary infection may be accompanied by a secondary trauma caused by the dressing adhering to the wound and, on removal, stripping newly formed tissue. This adhesion is normally caused by the adhesiveness of the drying exudate, and the trauma can be exaggerated on removal by the destruction of capillary loops that have penetrated the dressing material. This produces a bleeding surface which,

at most, may revert the wound to the primary inflammatory phase and, at least, delay epithelization.

Although not associated with the production of an acceptable microenvironment, there are certain physical characteristics that are required to assist in the overall dressing procedure. The dressing should have (11): 1) a size range to match the wounds; 2) an absorption range for dry and heavy exudate wounds; 3) good conformability and good handle when both dry and wet; 4) sterility and be stable in storage; 5) ease in disposability.

These parameters stimulated the development of functional and well-designed products using the advances that had accrued in the technology of materials. As an example, two-layered systems were recommended, consisting of primary and secondary materials. The primary dressing should meet the requirements of permeability, nonadherence, and bacterial impermeability, and the secondary, the need for absorption, protection, and insulation. This development was closely followed by products that were derived from the advances in the development of synthetic polymers. A statement of required performance could now be considered as a possible specification for a polymeric product.

The range of polymeric products produced as surgical dressings have included vapor-permeable films, polymeric foams, particulate and fibrous polymers, xerogels and hydrogels, and hydrocolloids.

These materials mark the progression towards the production of an *ideal wound dressing*. It should, however, be emphasized that no *single* dressing will produce the optimum microenvironment for *all* wounds or for all of the healing stages of *one* wound. The spectrum of performance requires that the wound is diagnosed and the treatment progressed by prescribing the most suitable dressing at each stage of the healing process.

This article will now examine the range of dressings currently available, identify their principal chemical and physical characteristics, and indicate their recommended clinical usage.

ABSORBENTS

The overall function of surgical absorbents is self-explanatory. They are required to absorb and retain a wide range of fluids from the blood and serous exudate of damaged tissue to the variable gut content met during surgical intervention (10, 13). They are available in a number of forms: 1) Fibrous (staple) absorbents, 2) Fabric absorbents, 3) Fiber plus fabric absorbents, and 4) Wound dressing pads.

Fibrous Absorbents

These are made from cotton staple or from the fibers of viscose or cellulose; viscose and cotton may be admixed.

Absorbent cotton is available in different qualities varying with the length and diameter of the cotton staple. It is available in the form of rolls and balls and is used for cleansing and swabbing wounds, for preparing preoperative skin, and for applying topical medicaments to the skin.

The absorption performance and physical character of *absorbent viscose* varies markedly with the manufacturing process. It is available in the bright or dull form, the latter containing a particulate material, such as titanium dioxide, within the fiber. The fibers are, in general, a continuous staple with a crenate transsectional profile, but smooth and luminated forms are available that show different degrees of absorptive capacity and wet tensile strength.

Some fibrous absorbents contain a proportion of acrylamide or other synthetic polymeric fiber. They frequently enhance the absorptive performance and give body to the fleece, thus improving fluid retention and

avoiding squeeze out, which is caused by fleece collapse after wetting.

Cellulose wadding is produced from delignified wood pulp and manufactured in a multiple laminate material form. It is used in large pieces to absorb large volumes of fluid in incontinence but is not used in contact with a wound unless enclosed in an outer fabric sleeve to prevent fiber loss to the wound.

Fabric Absorbents

Absorbent lint is a close weave cotton cloth with a raised nap on one side that offers a large surface area for evaporation when placed with the nap upwards on an exuding wound. It is generally unacceptable in modern wound management.

Absorbent gauze is the most widely used absorbent and consists of a cotton cloth of plain weave that is bleached white, is clean, and is reasonably free from weaving defects and contains not more than traces of leaf residue, seed coat, and other impurities (6). It may be slightly off white if sterilized. It absorbs water readily, but its performance may be reduced by prolonged storage or exposure to heat.

Gauze products are primarily absorbents when used preoperatively, perioperatively, and postoperatively, but perioperatively, they are also required to perform other functions, including the protection of tissue and organs by occluding areas not involved in the procedure, to assist the application of wet heat, which may establish the viability of doubtful tissue, and to assist in blunt dissection where fascias are separated along the lines of cleavage, thus avoiding unnecessary cutting (14).

The gauze fabric may contain a proportion of viscose incorporated with the cotton either in the warp and the weft or exclusively in the weft. A maximum level of 45% of viscose is widely accepted. A range of gauze fabrics exist that are graded according to the number of threads per 10 cm width of gauze.

Gauze products fall into two broad categories—the “swab” or “sponge” type produced by folding and stitching the cloth and the “plain cloth” type. The “swab” type includes swabs, strips, pads, and pledgets. The plain type includes packs and ribbon. Gauze swabs or sponges are commercially available as gauze folded into rectangles or squares to give various sizes or ply. They are folded in such a way that no cut edges are visible and the edges may be stitched. For use in an operating theatre, they are available with and without a radio opaque (X-ray detectable) mono- or multi-filament thread containing barium sulphate woven into or heat bonded to the fabric.

Table 1 Absorbent gauze

Type	Threads per 10 cm		
	Warp	Weft	Weight (g/m ²)
13 Light	73	57	14
13 Heavy	70	60	17
17	100	70	23
18	100	80	24
20	120	80	27
22	120	100	30
24a	120	120	32
24b	140	100	32

The commercial product can vary in size from 5 × 5 cm to 10 × 15 cm with a variation in ply from 4 to 32. Some are colored with a suitable fast, nontoxic dye.

Nonwoven fabrics include a wide range of products manufactured from synthetic and semisynthetic fibers.

Nonwoven swabs consist of a nonwoven viscose fabric and are available in folded pieces of various dimensions. These are occasionally used in error as a single wound dressing. They have a lower total absorbent capacity than gauze but absorb more quickly because of the random orientation of the viscose fibers. As fabrics, they constitute the outer layer on a number of wound dressing pads and are sometimes suitably coated with a polymer to reduce adherence at dressing change.

The types as defined in Table 1 are derived from the *European Pharmacopoeia* (15) and the designation of type numbers is one-tenth of the sum of the threads in warp and weft.

Absorbent muslin is a bleached cotton cloth of open weave used infrequently for the treatment of extensive burns and as a wet dressing.

Cellulose sponge is a cavity foam cellulose-based sponge available in sheets and thin bands. It is used to absorb at small sites in surgery. The material is not radio opaque and has a tendency to lose particles. Additional precautions must, therefore, be taken if such surgical use is contemplated.

Neuropatties are small squares or strips of nonwoven absorbent viscose with thread stitched through the nonwoven fabric and left long. These are used as spot absorbents, particularly in neurosurgery. They are frequently moistened in saline before application. The threads are left outside the surgical area, and on completion of surgery, the recovery of each pattie is facilitated by lifting each thread. Products vary in size and shape, and there may also be a device for attaching the ends of all the threads, thus producing a mini count rack.

Fibrous and Fabric Absorbents

Gauze and cellulose wadding consists of a thick layer of cellulose wadding enclosed in a tubular form gauze. The properties of the two separate materials have already been described. The gauze and cellulose wadding tissue is used as an absorbent and protective pad. It should only be used as a wound dressing with a nonadherent layer placed between the pad and the wound. It has a high absorbency, and because of its thickness, the additional property of insulation, which results in raising the temperature at skin surface, has been shown to accelerate the wound healing rate. On a highly exuding surface, there is a tendency for the cellulose wadding element to collapse when wet and become a semisolid wet mass. This may cause difficulty in practice. In such high fluid loss situations, the gauze and cotton tissue is preferred.

Gauze and cotton tissue (Gamgee tissue) is a thick layer of absorbent cotton enclosed in a tubular form gauze. It has the same uses as gauze and cellulose wadding tissue but has the advantage of a higher absorbent capacity and less wet collapse. It is also softer in use and, thus, conforms more readily to the wound surface. It should be used in place of gauze and cellulose wadding tissue on high exuding surfaces, such as burns, but as previously stated for gauze and cellulose wadding tissue, it should not be used in direct contact with the wound surface but placed upon a nonadherent primary dressing.

Wound Dressing Pads

Wound dressing pads are widely available in a number of formulations, which include the fibrous and fabric absorbents previously described plus other materials combined to meet some aspects of the acceptable performance profile. The pads can be subdivided into the following categories:

- absorbents and filmated products
- sleeved pads with a single layer core
- sleeved pads with a multiple layer core
- low adherence pads.

The absorbents and filmated products have been described. The simplest sleeved pads contain cotton, viscose, or cellulose fiber with an outer sleeve of gauze or nonwoven material. Those with a multilayer core have an outer sleeve of cotton, viscose, or nonwoven fabric that may have been treated with a polymer, such as polypropylene, to reduce adherence. The multilayer core is designed to increase absorptive capacity and to prolong usage by delaying *strike-through* to the outer surface. This is facilitated by using a fluid-retardant layer within the

upper and outer sleeve, which encourages lateral movement of fluid within the pad.

Low-adherence pads have wound contact faces designed to be of low adherence. They vary from aluminum-coated fabrics to perforated polymeric films or heat-bonded polyethylene films. The wound contact film may be attached to an absorbent fibrous mat and an outer woven or nonwoven fabric. In some products, the polymeric film forms a continuous sleeve on both dressing surfaces. They are dressings for low exudate and drying wounds where high adherence can be expected. These low-adherence, low-absorptive capacity dressings are sometimes centered on an adhesive backing to produce an *island* dressing, which is presented as a postoperative adhesive dressing or in the more familiar form of a first aid island or strip dressing for superficial injuries.

Low-adherence primary dressings consist of a partially open cellstructured nylon or viscose fabric that may be finished with a silicone coating. The open cell structure allows fluid transmission to a superimposed absorbent dressing pad. The pad is changed when required without disturbing the primary contact layer.

Deodorizing Dressings

Deodorizing dressings have been formulated from high gaseous sorbative activated-charcoal presented either as a woven fabric or a fibrous mat backed by a nylon sleeve, as a vapor permeable film, or as a polyurethane foam. In each formulation, the objective is to reduce odor, and the dressings must, therefore, be large enough to cover the entire malodorous area. One product encourages direct contact of the carbon layer with the wound exudate and whereas this will limit gaseous absorption, it is claimed that the incorporation of bound silver into the charcoal cloth inactivates bacteria that are absorbed onto the fabric surface, thus reducing the infective level and resulting in a reduction of odor.

POLYMERIC DRESSINGS

Vapor-Permeable Films

Vapor-permeable films are of use in those wounds in which granulation tissue is established and wound exudate is declining (16). These products have been developed as materials that would, in part, mimic the performance of skin. The resultant products were transparent, synthetic, adhesive films generically described as vapor-permeable adhesive membranes and consisting of transparent polyurethane or other synthetic film of low reflectance

evenly coated on one side with a synthetic adhesive mass. The adhesive is cohesive and inactivated by contact with moisture and will not, therefore, stick to moist skin or the wound bed. The films are permeable to water vapor, oxygen, and carbon dioxide but occlusive to water and bacteria. They have highly elastomeric and extensible properties that contribute to both their conformability and their resistance to shear and tear. The products are sterile and particle free.

The films also possess permeability functions that are essential to their efficacy as wound management material. It should be noted that the removal of the stratum corneum results in a water vapor loss from tissues of between 3000 g m² and 5000 g m² over a period of 24 h. This loss will result in progressive dehydration that could be of great significance, particularly in a full thickness burn. The loss through a positioned vapor-permeable membrane is reduced to 2500 g m² over 24 h or less, depending upon the structure of the membrane. This allows excess fluid to be lost by water vapor transmission through the membrane but prevents dehydration and maintains a moist wound interface. Where the volume of exudate produced is significantly greater than the volume removed as vapor, the water impermeability will result in serous effusion accumulating below the film. Impermeability to water prevents wetting from external sources.

The importance of a moist interface to wound healing is now well recognized. It allows the rapid migration of new epithelium across the wound surface, precludes trauma due to adherence at dressing change, and contributes to gaseous diffusion in the damaged tissue. Oxygen and carbon dioxide transfer are accomplished by intramolecular diffusion through the membrane and by solution in the wound surface moisture. The oxygen permeability of the films is variously described as 4000–10,000 cm³ m² 24 h at ambient temperature. The pO₂ and pH levels of the wound surface are directly related to the gaseous permeability and contribute to cellular activity. The wound is protected against secondary infection by the bacterial impermeability of the film to such organisms as *Pseudomonas aeruginosa*, *Staphylococcus aureus*, and *Eschericia coli*.

The physical performance is applicable to the management of superficial tangential wounds, such as dermabrasions, split skin graft donor sites, and burns. In a dermabrasion, haemostasis must first be obtained and the margin of the wound dried before the film is applied. Providing the film is correctly positioned, it may be left in situ until epithelization is complete. In its application for the treatment of burns, careful disinfection must precede the positioning of the film. It is only recommended for superficial and clinically clean burns and contraindicated

for deep burns where it retards the separation of necrotic tissue.

Decubitus ulcers and pressure sores can be covered with a vapor-permeable film, with the added advantage that the films' resistance to shear and low frictional surface properties protect the dermal layers from additional physical abrasion while producing the minimal barrier to normal skin function. This performance allows the film to be used as a prophylactic in areas that are traumatized by pressure but not ulcerated.

The film dressings can also be used for the retention of canulae and tubes in both ward and theatre. Specific products have now been produced with a variable water vapor permeability to reduce the build-up of moisture beneath the film and the resultant infective hazard.

In theatre, the large, synthetic, adhesive vapor-permeable films were originally used as incise drapes to protect tissue against additional trauma and were used postsurgery as a direct dressing over suture lines, allowing postoperative inspection without disturbing the area.

Polymeric Foams

These materials demonstrate the greatest variability between products. At their simplest, they are foamed polymers that have been made into sheets. The wound contact layer is often heat treated to give a smooth surface that absorbs fluids by capillarity. Foaming the polymer creates small, open cells that are able to hold fluids, and the cell size may be controlled during the foaming process. The most common polymer used is polyurethane. Their structure and softness also provide a cushion that protects and contributes to thermal insulation of the wound. They also may be tailored for particular applications, such as tracheostomy dressing, without particle loss to the wound and with the retention of their conformable characteristics. The nonadhesive foams will require a secondary dressing.

The dressings are available as sheet dressings and as *in situ* formed foams. They have a nonadherent wound contact surface and are also available as adhesive island dressings and cavity fillers (16). They are absorbent dressings used for wounds with moderate-to-heavy exudation.

The sheet dressings are, in the main, polyurethane foams where the absorbency and water vapor permeability are varied either by a physical modification to the foam or by combining the foam with an additional sheet component.

An early foam dressing consisted of a hydrophobic polyurethane foam, where one surface had been heat- and pressure-modified to produce a hydrophilic porous membrane about 0.5 mm thick. The outer surface of the

dressing consists of a layer of relatively large cells of approximately 5 mm thick and remains hydrophobic. Absorption of serous exudate is limited to the wound/dressing interface. In use, the absorptive capacity of the hydrophobic portion will be exceeded in a high exudate wound, and although moisture vapor transmission occurs through the dressing, frequent changes may be required until the exudate level diminishes. The superpositioning of a secondary absorbent pad will solve the problem of excess exudate while retaining the nonadherence, bacterial impermeability, gaseous and water vapor permeability functions and the additional cushioning and thermal insulation properties of the foam. The dressing combines the function of absorbency with that of producing an acceptable microenvironment that will allow healing to take place at the fastest rate concomitant with the total clinical condition of the patient.

Polyurethane foam dressings of this type are recommended for the management of dry sutured wounds, minor lacerations, early pressure ulcers, and venous ulcers (17, 18).

A partially expanded, modified polyurethane foam was developed by Lock (12). It comprised a lower layer of open cells and an upper hydrophilic surface with closed impermeable layers that reduce the loss of water vapor and prevent strike through of absorbed fluid. This primary dressing expands when it becomes wet and conforms to the contours of the wound, producing an environmental chamber with entrapped solutes and cell debris. It is claimed that this function enhances the inflammatory response of the wound and, subsequently, stimulates the production of granulation tissue and revascularization. These polyurethane membranes are recommended specifically for the management of stasis ulcers, with a superimposed absorbent pad and graduated pressure applied either by stretch bandages or elasticated stockings.

A foam dressing with the prime function of absorbency has been designed for the management of burns. It consists of a highly absorbent hydrophilic polyurethane foam backed with a moisture-permeable polyurethane membrane and bonded to an apertured polyurethane net on the wound contact face. It is capable of absorbing and retaining large volumes of fluid even under pressure. The backing, while permeable to water vapor, is impermeable to water, thus avoiding strike through. As the exudate level decreases, the membrane retains moisture and prevents the drying of the wound. The apertured polyurethane net interface reduces adherence to the wound surface. Whilst recommended for burns, these dressings have been used successfully on other exuding lesions (19).

Low-absorptive capacity, primary foam dressings have been produced from a carboxylated styrene

butadiene rubber latex foam. The foam is bonded to a nonwoven fabric coated with a polyethylene film that has been vacuum ruptured. The basic foam is naturally hydrophobic, and a surface active agent is incorporated to facilitate the uptake of wound exudate. The polyethylene foam layer is particularly effective in preventing adherence, and the dressing is recommended for minor wounds and abrasions where exudate levels are low and adherence a prominent hazard at dressing change.

In Situ Foam

One of the major problems in wound management is the treatment of large cavity wounds produced either postoperatively, such as a pilonidal sinus, or by trauma, such as pressure ulceration. It is necessary to occlude the cavity by packing to absorb excess exudate and to stimulate the production of granulation tissue, neovascularization, and collagen deposition.

The traditional procedure is to pack the cavity with ribbon gauze (see Fibrous Absorbents) variously impregnated. The subsequent removal of such a dressing is difficult, and the pain and stress associated with the dressing change may require low-level anesthesia and theatre management.

An in situ-formed foam was originally designed by Dow Corning and found to be clinically superior to ribbon gauze (20). Its status in cytotoxic terms was in dispute, but it is now available as Cavi-Care™ (Smith & Nephew), and its exclusion would be to the detriment of this chapter.

Cavi-Care foam dressing is a two-part foam composed of a filled poly(dimethylsiloxane) base and a stannous octonate catalyst. The two components are mixed together immediately prior to use. The reaction is slightly exothermic and over a period of 2–3 min, the dressing expands to approximately 4 times its original volume and sets to a soft, spongy foam accurately conforming to the contours of the wound cavity. The stent is normally removed twice daily, soaked in a mild antiseptic (0.5% aqueous chlorhexidine), rinsed in cold running water, squeezed dry, and replaced. A new dressing is formed after a week or more to match the reduction in size of the cavity. The product does not adhere to granulation tissue. It maintains free drainage around the wound and has a low, but significant, absorptive capacity at the dressing surface. It has been indicated for the management of pilonidal sinus, hydradenitis suppurativa, perianal and perineal wounds, and in the management of dehiscent abdominal wounds.

Hydropolymer

Hydropolymer appears visually as a foam but is described as a foamed gel. The material expands into the contours of the wound as it absorbs fluid, and is used in an island configuration with an adhesive portion, which is unique. It has the ability to re-adhere once lifted, enabling manipulation of the product for fit or assessment of the wound without dressing change. The hydropolymer wicks fluid into the upper layers of the dressing where it escapes through the backing (21).

Its recommended use is for dynamic fluid management for heavily exuding wounds or where extended periods between dressing changes are desirable.

Hydrogels

Hydrogels, or water polymer gels, are modified, cross-linked polymeric formulations that form 3D networks of hydrophilic polymers prepared from materials such as gelatin, polysaccharides, cross-linked polyacrylamide polymers, polyelectrolyte complexes, and polymers or copolymers derived from methacrylate esters. These interact with aqueous solutions by swelling to an equilibrium value and retain a significant proportion of water within their structure. They are insoluble in water. Hydrogels are available in dry or hydrated sheets or as a hydrated gels in applicators. When hydrated, they contain up to 96% water and have additional, high, absorption properties.

The physical properties of bulk polymers are directly influenced by a number of factors including the nature of monomers, copolymers, the cross-linkers and the degree of cross-linking and the polymerization initiators and processing parameters. The availability of hydrophilic and hydrophobic sites is influenced by the chain of configuration and conformation and could determine the degree of hydrophilicity and oxygen permeability. By varying the nature of the polymer backbone, a range of water-binding behavior and, thus, mechanical, surface, and permeability properties can be obtained. The expanded nature of the hydrogel structure and its permeability allows the extraction and polymerization of initiator molecules, initiator decomposition products, and other extraneous materials from the gel network before the hydrogel is placed in contact with the living system. The tissue-like structure of most hydrogels will contribute to their biocompatibility by minimizing mechanical irritation to surrounding cells and tissues. They possess low interfacial free energies with aqueous solutions and only a weak tendency to absorb biological species, such as proteins or cells. Their high moisture

content maintains a desirable moist interface that facilitates cell migration and prevents dressing adherence. Water can be transmitted through the saturated gel; whereas the unsaturated gel will have a water vapor permeability comparable with the water vapor permeability of vapor-permeable membranes.

The absorption, transmission, and permeability performance result in the maintenance of a moist wound with a continuous moisture flux across the dressing and a sorption gradient that assists in the removal of toxic components from the wound area. The high moisture content allows dissolved oxygen permeability, which varies between products but will allow the continuation of aerobic function at the wound/dressing interface and have an effect upon both epithelization and bacterial growth. It has been observed that the positioning of a hydrogel frequently results in a marked reduction in pain response in patients. It is suggested that the high humidity protects the exposed neurones from dehydration and also produces acceptable changes in pH. A secondary effect that may contribute to this response is the property of the gels to immediately cool the wound surface and maintain a lower temperature for up to 6 h (22). This lowering of temperature could result in a reduction of the inflammatory response.

Sheet hydrogels

Sheet hydrogels are sheets of 3D networks of cross-linked hydrophilic polymers (polyethylene oxide, polyacrylamides, polyvinylpyrrolidone, carboxymethylcellulose, modified corn starch). Their formulation may incorporate up to 96% bound water, but they are insoluble in water and interact by 3D swelling with aqueous solutions. The polymer physically entraps water to form a solid sheet, which may make them feel moist but compression of the sheet will not release any water. They have a thermal capacity that provides initial cooling to the wound surface. A secondary dressing is required.

The recommendation for use of these products includes the management of donor sites and superficial operation sites and also the treatment of fresh, chronic damaged epithelium, such as thermal and other painful wounds, and dermatitic skin where the avoidance of topical agents is indicated. In chronic ulcers, they are used to encourage granulation and formation of cellular tissue.

Amorphous hydrogels

Amorphous hydrogels have additional ingredients, such as alginate, collagen, or complex carbohydrates, besides water and a polymer. They are similar in composition to sheet hydrogels, but the polymer has not been cross-

linked. These amorphous preparations do not have the cooling properties of the sheet dressings, and a secondary dressing is required. Their recommended use includes hydration of dry, sloughy, or necrotic wounds and autolytic debridement.

One of the earliest hydrogel dressings came from Hydro Med Sciences, Inc., NJ, USA. It is formed directly on the wound by using a two-component spray system, consisting of p(HEMA) and polyethylene glycol (PEG). Alternate layers are applied to the wound. The PEG dissolves the p(HEMA), forming a saturated solution that solidifies after 30 min (23).

A primary hydrogel dressing has been produced from a colloidal suspension of radiation cross-linked polyethylene oxide and water with an equilibrium water content of 96%. The gel is sandwiched between polyethylene films. The wound contact film is routinely removed, and the outer film is used to control evaporation from the gel surface (24, 25). A novel hydrogel was developed by the Max Plank Institute for Immunobiology and Dermatology consisting of an insoluble cross-linked polyacrylamide agarose polymer containing 95% water as the disperse phase (26). The gel has a high elasticity and tensile strength and a high capacity to absorb exudate from wounds. It is available in hydrated and dehydrated forms and as granules which, with their increased surface area, absorb larger amounts of exudate. The granules can be used to fill a cavity wound with the gel sheet superimposed to produce a continuous hydrogel dressing.

An alternative to the acrylamide-based composite hydrogel dressing is an acrylamide grafted to a polyurethane film to give a transparent, flexible gel with an equilibrium water content of approximately 50%. The hydrated gel has a low modulus of elasticity and a high water permeability, which facilitates the adherence of the gel to the wound surface. The permeability characteristics allow penetration of antimicrobial agents, which can be applied topically to the dressing surface in situ.

Particulate and Fibrous Polymers

This group of dressings includes synthetic, semisynthetic, and naturally occurring products embracing a range of polysaccharide materials.

Xerogels

The xerogel dressings may be regarded as a subgroup of products within the larger group of polysaccharide dressings. The latter contains the well-known cellulosic

dressing products, such as gauze and absorbent cotton (see Absorbents section), but the products that consist of dextranomer beads, dehydrated hydrogels of the agar/acrylamide group, calcium alginate fibers, and dehydrated granulated Graft T starch polymers are identified specifically as xerogels (27), the material remaining after the removal of most or all of the water from a hydrogel (or the disperse phase from any type of simple gel). These materials, therefore, have no water in their formulation but swell to form a gel when in contact with aqueous solutions.

Particulate Polymers

Dextranomer

This xerogel is a polymer of the polysaccharide dextran, a naturally derived polymer of glucose produced by cultures of a microorganism, *Leuconostoc mesenteroides*. The gel is formed when the dextran molecules comprising the disperse phase of the hydrocolloid are cross-linked by a chemical process utilizing epichlorhydrin and sodium hydroxide (27). Dextranomer is available as beads or paste. The material requires a secondary dressing.

The dextranomer is supplied in beads of 100–300 μm diameter containing poloxamer 187, polyethylene glycol 300, and some water. A paste formulation is also available, which is the dextranomer in polyethylene glycol 600 (PEG 600). The beads are offered as a discrete particle or enclosed in a low adherence pouch for insertion into a cavity wound. One company (Pharmacia & Upjohn) offers a polymeric net that can be placed into a cavity wound before the addition of either granules or paste and facilitates removal and also a vapor-permeable film that is superimposed on the dextranomer dressing to control evaporation and retard the drying of the dextranomer in a low exudating wound. The hydrophilic beads will absorb the aqueous component of wound exudate and dissolved materials ranging from inorganic salts to low molecular weight proteins. Dextranomer has a pore size that produces an exclusion limit of 1,000–8,000 Da, which precludes the sorption of viruses and bacteria. Microorganisms are removed from the wound by the capillary action between the beads, a function that is absent from the paste formulation which, however, demonstrates a marked increase in absorbing capacity for malodorous elements and pain producing compounds released during the inflammatory response.

Dextranomer is used primarily as a debriding agent on sloughy and exuding wounds, whether clean or infected, and on small area burns, where the objective is to produce

a clean tissue bed for the production of a granulating tissue. It is not a product that should be used beyond this phase as its continued application will impair epithelization. Dextranomer is *not* biodegradable, and both granules and paste must be carefully removed with Normal saline before drying to avoid particulate residues and the subsequent development of granulomas.

The use of dextranomer on exuding necrotic injuries, such as leg ulcers, has proved to be beneficial, and it is an acceptable substitute for surgical or enzymatic debridement. The granules are contraindicated in drying wounds.

Fibrous Polymers

Alginate dressings

Alginic acid is a polyuronic acid composed of residues of D-mannuronic acid and L-guluronic acid and is obtained chiefly from algae belonging to the Phaeophyceae, mainly species of *Laminaria*.

Calcium alginate dressings are flat, nonwoven pads of either calcium sodium alginate fiber or pure calcium alginate fiber. The alginate wound contact layer may be bonded to a secondary absorbent viscose pad. Alginate hanks are also available, as are packing and ribbon for deeper cavity wounds and sinuses. Alginates have been shown to be effective in the management of injuries where there has been substantial tissue loss. The nonadhesive formulations require a secondary dressing.

Gel formation is via ion exchange. A biodegradable gel is formed when the fiber is in contact with exudate and the calcium contributes to the clotting mechanism. The gel may be firm or soft, depending upon the proportions of calcium and sodium in the fiber. The gel is removed with saline.

The isomeric acids are present in varying proportions, depending upon the seaweed source. Calcium alginate is capable of gel formation. The guluronic acid forms an association with calcium, providing the stimulus to produce the continuous disperse phase of a hydrogel. Ca^{2+} ion and a phospholipid surface promote the activation of prothrombin in the clotting cascade, and calcium alginate products are used as the source of these ions to arrest bleeding, both in superficial injuries and as an absorbable haemostat in surgery. The rate of biodegradation is related to the sodium/calcium balance in the preparation.

The alginates are produced in fiber form and presented as a fleece or layered needled fabric. When applied to a bleeding surface, both the availability of the Ca^{2+} ions and the fibrous matrix contribute to coagulation and serum absorption produces a gel-like mass. The dressings may be

removed with a sterile 3% sodium citrate solution, followed by washing with sterile water, or they may be removed with sterile Normal saline.

The *wet* integrity of the dressing, which facilitates removal from the wound, may be improved by incorporating fibers of greater strength, such as viscose (rayon) staple fiber, or fibers that interact with the alginate fibers when wet, such as chitosan staple fibers (28).

The primary haemostatic usage of calcium alginate is in the packing of sinuses, fistulae, and bleeding tooth sockets. The alginate dressings have recently become widely used as a soluble wound packing for a number of additional wound types. They have been used as a useful nonadherent for lacerations and abrasions and are effective in the management of hypergranulation tissue (proud flesh), interdigital maceration, and heloma molle. The hospital and community use of calcium alginate includes intractable skin ulcers and pressure sores, where they would appear to accelerate healing, and in the successful management of diabetic ulcers, venous ulcers, burns, and infected surgical wounds.

Alginates have proved to be useful debriding agents. When applied to these injury types, the alginate must be covered by a secondary dressing of foam or film. Some proprietary products bond calcium alginate to a secondary backing, such as absorbent viscose pad or semipermeable adhesive foam, to produce an island dressing.

Hydrocolloids

Hydrocolloid dressings consist of composite products based on naturally occurring hydrophilic polymers. Generally, these dressings are flexible, highly absorbent, occlusive or semiocclusive adhesive pads formulated from biocompatible hydrophilic polymers, such as sodium carboxymethylcellulose, hydroxyethylcellulose, pectins and gelatin incorporated into a hydrophobic adhesive. The dressings may be backed by a polymeric film and may be contoured to fit difficult areas. Hydrocolloids are also available as pastes or powders or gels. The pads do not require a secondary dressing.

In general, hydrocolloids consist of first, a pressure-sensitive, adhesive layer, composed of a so-called *hydrocolloid* dispersed with the aid of a tackifier in an elastomer and secondly, a film coating, composed of a gas-permeable but water-impermeable, flexible, elastomeric material. One of the first hydrocolloid dressings described had a pressure-sensitive, adhesive hydrocolloid layer which consisted of 40–50% by weight of a mixture of gelatin and sodium carboxymethylcellulose dispersed in polyisobutylene with an antioxidant and a tackifier (mineral oil and terpene resin). This was then laminated

with a semi open cell, flexible, polyurethane foam that had previously been laminated with a flexible, polyurethane film. A currently available hydrocolloid dressing is a flexible mass with an adherent inner face and an outer semipermeable polyurethane foam.

The modified formulation is as follows:

Sodium carboxymethylcellulose	20%
Polyisobutylene	40%
Gelatin	20%
Pectin	20%

The product is also available as granules of similar formulation, allowing a continuous *fill* for cavity wounds.

Other hydrocolloid dressings, with formulations consisting of sodium carboxymethylcellulose combined with karaya gum or sodium carboxymethylcellulose on its own, are also available.

The adhesive formulation of hydrocolloids gives an initial adhesion higher than some surgical adhesive tapes. After application, the absorption of transepidermal water vapor modifies the adhesive flow to maintain a high tack performance throughout the period of use. In situ, the dressings provide a gaseous and moisture-proof environmental chamber that strongly adheres to the area surrounding the wound, offering protection against contamination from incontinence or other sources. In the wound contact area, the exudate is absorbed to form a gel that swells in a linear fashion with a higher moisture retention at the contact surface. This results in an expansion of the gel into the wound cavity with the continued support and increasing pressure from the remainder of the elastomeric dressing. The larger the volume of exudate, the greater the expansion into the cavity, up to the limitation imposed by the availability of the gel. The advantage of this system is that it applies a firm pressure to the floor of a deep ulcer, a basic surgical maxim for the production of healthy granulating tissue. It is this function that contributes to the recommended usage for venous ulcers (29).

The formed *colloidal* gel also produces a sorption gradient for soluble components within the serous exudate and allows the removal of toxic compounds arising from bacterial or cellular destruction. The moist gel is soft and conforms to the wound contours. When the dressing is removed, the gel remains in the wound and can be washed away with Normal saline. During use, the dressing in contact with the wound liquefies to produce a pus-like liquid with a somewhat strong odor. The hydrocolloids are suitable for desloughing and for light-to-medium exuding wounds, but are contraindicated if an anaerobic infection is present. They have been used successfully in the

treatment of chronic leg ulcers, pressure ulcers, and as skin barriers in the management of stoma.

As with the hydrogels, the products can be obtained in both powder and paste form, where the powders and pastes have similar formulations to that of the hydrocolloid mass in the sheet dressing. This will allow larger cavity wounds and heavily exuding wounds to be treated with a continuous hydrocolloid system. The recommended use for these dressings is for the treatment of pressure ulcers, minor burns, granulating wounds, and wounds exhibiting slough or necrotic tissue, or wounds with moderate exudate.

Superabsorbents

Superabsorbents are hydrocolloidal compounds that have a high absorbent capacity and entrap exudate so that it cannot be squeezed out once absorbed. One product incorporates this material into an island pad that is covered by a nonwoven absorbent and surrounded by an extra-thin hydrocolloid as the adhesive portion. The covering acts as a transfer layer while its surface stays dry. Superabsorbents are recommended for use with heavily exuding ulcers (16).

Hydrofibers

Hydrofibers are fibers of carboxymethylcellulose formed into flat, nonwoven pads with the facility to form a gel in contact with fluid. The absorbent rate and capacity is approximately 3× that of calcium alginate. The resultant gel is similar to a sheet hydrogel, which does not dry out or wick laterally. Therefore, there is no maceration of the skin surrounding the wound, but moisture is maintained in contact with the wound bed. The high absorbent capacity reduces the frequency of dressing changes. Hydrofibers are recommended for use with heavily exuding wounds or wounds where an extended wear time is desired (16).

Impregnated Dressings

Impregnated dressings coat the area of the wound with hydrophobic paraffin spread on an open mesh gauze, thereby providing both insulation and partial occlusion but allowing excess exudate to be absorbed by a superimposed absorbent pad. Impregnated dressings have the advantage of low adherence and allow gaseous diffusion, but the disadvantages include the incorporation of the soft paraffin or loose cotton fibers into the healing wound, thereby producing a *foreign body* response within the wound, leading to an extended inflammatory phase with

consequent delayed wound healing. These products also, when used excessively, retain wound exudate causing maceration to the surrounding, otherwise healthy, tissue.

Close weave gauze and open weave tulles are used as carriers of medicated and unmedicated ointments to the wound surface.

Paraffin gauze (Tulle) dressing

Paraffin gauze is bleached cotton or a combination cotton and rayon cloth impregnated with yellow or white soft paraffin. It is available as sterile single pieces or multipacks. The paraffin is present to prevent the dressing adhering to a wound. The gauze, which may be leno in nature, is coated so that all the threads of the fabric are impregnated but the spaces between the threads are free of paraffin. The material is used primarily in the treatment of wounds such as burns and scalds where the protective function of the stratum corneum is lost and water vapor can escape from the body surface. Paraffin gauze dressing functions by reducing the fluid loss while the water barrier layer is reforming. The two properties of the paraffin gauze that are most useful are those of nonadherence and semi-occlusiveness.

In addition to its application to burns and scalds, paraffin gauze dressing is used as a wound contact layer in lacerations, abrasions, and in ulcers, where it is used as a packing material to promote granulation. Postoperatively, it is used as a vaginal or penial dressing and for sinus packing.

Povidone iodine 10% w/w, chlorhexidine 0.5% w/w, sodium fusidate 2% w/w, and framycetin sulfate 1% w/w are some examples of available impregnations that are recommended for the reduction of infection. Diffusion of the antibacterial agent into or onto an infected and exuding wound has been shown to be minimal. The possibility of development of resistant strains of infective organisms has reduced the usage of these products.

Biodressings

Biodressings are composed of materials that are almost exclusively originated from living tissue and are said to “participate actively and beneficially in the biochemistry and cellular activity of wound healing” (30). They can be identified as biological dressings and biosynthetic dressings and the biological dressings can be further subdivided into natural or cultured, depending on their origin.

Collagen dressings (biosynthetic dressings)

Collagen dressings are formed from denatured collagen peptides, derived from pig skin, and purified bovine hide collagen, cross-linked with the glycosaminoglycan,

chondroitin-6-sulfate. When applied to damaged tissue, the dressings stimulate the production of fibroblasts and endothelial cells while accelerating the migration of epithelial cells. These biological components are combined with silicone elastomers to control moisture vapor loss during the accelerated growth period (31).

The bovine material used for the extraction of the Type-1 collagen used in these dressings is nonantigenic due to enzymatic purification. It is available as sheets, particles, pastes, or gels. The dry materials absorb exudate to form a gel, and it is believed that the addition of collagen to a wound bed accelerates wound repair by the provision of a matrix for cellular migration (16). One manufacturer has incorporated 10% alginate in the dressing formulation. The materials all require a secondary dressing and are recommended for use on any recalcitrant wound.

Natural biological dressings

Autologous (self) skin is harvested from a healthy area of the patient's body and transferred to the wound, generally a burn. The procedure leaves a second injury or donor site. The advantages of nonallergenicity, nontoxicity, nonpyrogenicity, and direct incorporation into the healed area with the overall performance parameters of intact skin make this the dressing of choice. Skin harvested from fresh cadavers and used as an allograft is a possible alternative to autologous skin. This skin undergoes processing to remove fibroblasts, endothelial cells, and epidermis, which would stimulate an immune response. The resulting product is an acellular, dermal collagen matrix that is immunologically inert but retains elastin, proteoglycans, and the basement membrane complex (31).

Porcine skin: Sterile, denatured lyophilized skin of porcine origin is produced and consists of the dermal and/or epidermal layers. The material is reconstituted by immersion in sterile water or saline and applied dermal side to the wound. A bovine preparation is also available. It is used as a temporary dressing in burns and ulcers, particularly where a site is being prepared for grafting.

Cultured biological dressings

Cultured biological dressings are derived from mammalian cell culture procedures that facilitate the development of sheets of cells derived from a few of the patients' own epidermal cells. Cultured human keratinocytes form cultured epithelial grafts which are not bioengineered tissue but are cultured cell products with limited use. These cultures may be regarded as a precursor, which has led to the development of other products through bioengineering (31).

Bilayered skin equivalent: A bilayered composite skin equivalent has been developed with a viable dermis and epidermis. The epidermis is composed from cornified differentiated keratinocytes and a dermal matrix composed of a collagen lattice containing viable fibroblasts. Its cellular components assist with wound closure through stimulation of the wound bed. The outer layer of the differentiated bilayered skin equivalent, the stratum corneum, acts as a specialized vapor-permeable membrane and protective outer barrier (31).

Human dermal replacement: Human dermal replacement requires cultivation of human diploid fibroblasts on a 3D polymer scaffold. The cells are derived from newborn foreskin and are living cells that are metabolically active following implantation into the wound bed (31).

Bioactive Dressings

The Introduction described the performance parameters of *interactive* dressings which distinguished them from the *passive* products. Current developments have confirmed that the next generation of products will participate actively in the wound healing process by contributing growth hormones, chemotactic agents, angiogenic agents, and other growth factors, either in a depot release mode or as sequentially released compounds (32), as well as controlling the microenvironment surrounding the wound.

Each wound management product will eventually be designed to meet the environmental, nutritional, and growth requirements of particular wound types and will probably be based on those biodressings described earlier. The group will be designated *bioactive* wound management products (33). These biodressings must be the precursors for the development of many more exciting products, which will improve the morbidity of wound healing to the advantage of both patient and clinician.

CONCLUSION

The content of this chapter has been restricted to those products that are in direct contact with the wound. There are many other products outside this limitation that are used successfully for wound management. These include surgical adhesive tapes and nonextensible, conforming, and elastic net bandages, used to retain dressings in position, and the extensible bandages, which may vary from the light support and compression products for the management of sprains and strains and the prevention of

edema to the high compression bandages used either alone or superimposed on various dressings to apply pressure to a limb.

DOSAGE FORMS: PARENTERALS

Gayle A. Brazeau

Adam Persky

Jintana M. Napaporn

University of Florida, Gainesville, Florida, U.S.A.

INTRODUCTION

Parenteral is derived from the two words “para” and “enteron” meaning to avoid the intestine. Parenteral articles are defined according to the USP 24/NF19 “as those preparations intended for injection through the skin or other external boundary tissue, rather than through the alimentary canal, so that the active substances they contain are administered using gravity or force directly into a blood vessel, organ, tissue, or lesion. Parenteral products are prepared scrupulously by methods designed to ensure that they meet pharmacopeial requirements for sterility, pyrogens, particulate matter, and other contaminants, and, where appropriate, contain inhibitors of growth of microorganisms. An injection is a preparation intended for parenteral administration and/or for constituting or diluting a parenteral article prior to administration” (1). Parenteral drug administration is an attractive route of administration when oral administration is contraindicated, and it has been traditionally used in institutional settings. With an increasing interest in reducing overall health care costs and with the development of new biotechnologically derived compounds and improved and novel infusion-related technologies, parenteral products have become an important component in the care of patients in hospitals and the home health care setting. In the present article, information will be presented on history and the following: the use of parenterals in health care, the advantages and disadvantages of using parenterals, routes of administration, vascular access devices and infusion sets, types of parenteral products, components of parenteral products, parenteral packaging, convenience and needleless systems, needleless injection, extemporaneous compounding of parenteral products, infusion pumps and devices, and future parenteral dosage forms.

HISTORY AND USE OF PARENTERALS

A detailed history of early parenteral medications can be found in the first edition of this encyclopedia (2). One of

the first historical references to the parenteral administration of a compound was in the late 15th century when a blood transfusion from three young boys was given to Pope Innocent VIII, resulting in the death of all four individuals. These deaths led to a ban in the use of this type of medical treatment, namely an infusion, for several centuries. It was not until the 17th century that studies on the parenteral administration of compounds was first studied in animals. The development of the hypodermic needle and the use of parenterally injected drugs in humans is first reported in the mid-19th century. By the end of this century, there was an increased interest in the use of intravenous administration of glucose and normal saline solutions. Baxter produced the first commercially prepared intravenous solutions in 1931. However, parenteral products and their administration became acceptable and a mainstay in the treatment of patients in the mid 20th century. This could be attributed, in part, to our increased understanding of microbial and viral agents, increased recognition of the dangers associated with parenteral therapy, the development of antibiotics and other drug classes, and the availability of new systems or infusion technologies. In the mid 1960s, many hospitals introduced intravenous admixture services. In the last 20 years, the area of infusion pumps and systems and improved vascular access devices has enabled parenteral therapy to extend beyond the institutional setting to clinics, ambulatory infusion centers, and home health care. In addition, the administration of parenteral drugs is also frequently utilized in basic and clinical research in animals and humans.

In today's health care environment, parenteral products are a key component of therapy for hospitalized patients. Vascular access for parenteral infusion therapy is obtained in the vast majority of hospitalized patients at some point in their therapy. There are very little data as to the use of parenteral products in today's health care environment. It was suggested that 40% of all pharmaceutical dosage forms are administered as a type of injection and that over 350 million units of large volume parenterals and 100 million units of IV admixtures (piggybacks) were used annually in the late 1980s (3). These numbers have

certainly increased since that time with the advent of new drugs and infusion methodologies. Infusion therapy in home health care continues to have a strong market in the United States. While the annual growth rate of home infusion therapy decreased between 1982 and 1993, 29% of acute care hospitals provided or were developing a home health care program. In the current market, home infusion therapy is being integrated into alternative sites, such as ambulatory infusion centers (4). Due to the rapid and increasing use of parenteral drugs, it is critical for health care providers and scientists to understand the various available dosage forms, specific products, routes of administration, catheter types, and various infusion devices. Detailed information on these devices can be found in the nursing and pharmaceutical literature (3, 5–10). In addition, company websites are a valuable source of current information, including available parenteral products, infusion sets and ports, devices and infusion pumps. A list of useful worldwide websites is shown in Table 1.

ADVANTAGES AND DISADVANTAGES OF PARENTERAL PRODUCTS

The advantages and disadvantages of parenteral drugs and administration are shown in Table 2. Generally, parenterally administered drugs are advantageous because they can provide rapid and reliable drug systemic effects, long-term drug delivery, and targeted drug delivery. The disadvantages of parenteral products are predominately associated with safety issues related to infection and thrombosis, tissue damage and/or pain upon injection, and the use of requirements for specific equipment, devices, and techniques.

ROUTES OF ADMINISTRATION

The routes of administration for parenteral products are shown in Fig. 1. The most commonly used routes are intravenous, intramuscular, subcutaneous, and intradermal. Formulations intended for administration into the central nervous system should not include preservatives. For intramuscular, intradermal, and subcutaneous, a single needle and syringe is generally used to administer the drugs. For intravenous and intra-arterial, drugs are administered using vascular access or port devices. Other parenteral routes of administration (e.g., epidural, intra-articular, and intrathecal) usually require specialized delivery sets. In some cases, the specific drug requires a

specialized delivery set be utilized due to the dose of the drug or the physicochemical properties of the drug (e.g., nitroglycerin).

VASCULAR ACCESS DEVICES AND INFUSION SETS

Vascular access can be achieved through short peripheral, long dwell peripheral, central lines, and ports (8, 11). These various devices differ in their insertion, characteristics, dwell time or time they should be in place, and usage and safety features. In peripheral access, the distal veins on the hand and arm are often used, with the basilic and cephalic veins in the arms being the most common site for peripheral infusions. Alternatively, the metacarpal veins can also be utilized. The basic devices are a winged infusion device or the over-the-catheter needle, with needle sizes ranging from 16 to 26 G (20- or 22-gauge being the most common size). These catheters are usually utilized only for 48 h. A midline catheter is usually inserted into a large vein and is intended to be used over a 2- to 4- week period (Richardson). Peripherally inserted central venous catheters (PICC) are designed for long-term infusion therapy up to a year. The devices are inserted into a peripheral vein and threaded so that the tip of the catheter is within the central vascular system. Central venous catheters (CVC) are inserted into the subclavian or jugular vein and threaded until the tip is located in the superior vena cava. The types of central venous catheter are a nontunneled, Groshong, Hickman, and Brovaic. A nontunneled CVC can be inserted at the bedside, whereas the Groshong, Hickman, and Brovaic require surgical insertion. Vascular access ports (VAP) are an alternative to central venous access. These devices are surgically implanted usually into the chest wall or arm subcutaneous tissue and are composed of a rigid reservoir with a self-sealing rubber septum, and the tip of the catheter is placed into a central vein. The drug is placed into the reservoir via an injection. A VAP allows repeated, intermittent access and drug delivery (in some cases up to 2000 times), depending upon the size of the needle. Examples of these types of ports include a P.A.S Port® (SIMS Deltec), Vital-Port® (Cook Incorporated), and BardPort® and CathLink® (Bard Medical Division).

There are three basic types of intravenous administration: 1) primary set, 2) secondary set, and 3) a volume control set (Fig. 2) (8). The basic components of all these sets include a piercing spike (to insert into the bag or bottle), drip chamber and drip orifice, tubing ranging in length from 160 to 250 cm (63–98.58 in.), a roller clamp

Table 2 Advantages and disadvantages of parenteral drugs and administration

Advantages	Disadvantages
Useful for patients who cannot take drugs orally	More expensive and costly to produce
Useful for drugs that require a rapid onset of action (primarily intravenous administration)	Potential for infection at site of injection
Useful for emergency situations	Potential for sepsis
Useful for providing sustained drug delivery (implants, intramuscular depot injections)	Potential for thrombophlebitis
Can be used for self-delivery of drugs (subcutaneous)	Potential for fluid overload
Useful for drugs that are inactivated in the gastrointestinal tract or susceptible to first-pass metabolism by the liver	Potential for air embolism
Useful for injection of drugs directly into a tissue (targeted drug delivery)	Potential for extravasation
Useful for delivering fluids, electrolytes, or nutrients (total parenteral nutrition to patients)	Psychological distress by the patient
Useful for providing precise drug delivery by intravenous injection or infusion utilizing pharmacokinetic techniques	Require specialized equipment, devices, and techniques to prepare and administer drugs
Can be done in hospitals, ambulatory infusion centers, and in home health care	Potential for pain upon injection
	Potential for tissue damage upon injection
	Risk of needlestick injuries and exposure to blood-borne pathogens by health care worker
	Increased morbidity associated with long-term vascular access devices
	Disposal of needles, syringes, and other infusion devices requires special consideration

or other flow control device on the tubing, a Y-site for infusion of other components, an in-line filter (ranging from 0.2 to 170 μm) and leuk-lok adapter to attach to the vascular access device. A primary infusion set is designed to deliver solutions from the parenteral container via gravity. If an additional infusion is needed, the secondary set can be connected to the primary set via one of the Y-sites. A volume control administration set is used to deliver a small amount of solution through the use of the volume chamber. In general, administration sets are classified into macrodrip sets that can deliver 10–20 drops/ml and a microdrip set that delivers drugs at a slower rate of 60 drops/ml.

TYPES OF PARENTERAL PRODUCTS

Parenteral products can be divided into two general classes according to the volume of the product. All parenteral products are sterilized and must meet all the requirements for sterility and particulate matter and must be pyrogen-free (36). They must be prepared using strict sanitation standards in environmentally controlled areas by individuals trained to meet these standards. The injections are overfilled with a small excess over the labeled volume to ensure that the required volume can be obtained from the product. *Small-volume parenterals (SVP)* or injections are 100 ml or less and can be provided as a single- or multidose

product. In contrast, *large-volume parenterals (LVP)* are intended to be used intravenously as a single-dose injection and contain more than 100 ml of solution. SVPs and LVPs are often combined during the extemporaneous preparation of intravenous admixtures, to be discussed later in this article.

The U.S. Pharmacopoeia (USP) classifies injections into five different types. The dosage form selected for a particular drug product is dependent upon the characteristics of the drug molecule (e.g., stability in solution, solubility, and injectability), the desired therapeutic effect of the product (e.g., immediate vs. sustained release), and the desired route of administration. Solutions and some emulsions (e.g., miscible with blood) can be injected via most parenteral routes of administration. Suspensions and solutions that are not miscible with blood (e.g., injections employing oleaginous vehicles) can be administered via intramuscular or subcutaneous injection but should not be given intravenously.

Parenteral products contain excipients such as buffers, solvents, nonaqueous solvents, antimicrobial preservatives, antioxidants, and chelating agents. Coloring agents are prohibited in parenteral products. All excipients must meet compendial standards, and the excipients must not interfere with the efficacy of the product (to be discussed more in detail later in this article). Parenterals are packaged in airtight containers using specific, high quality materials so that they do not interact with the product and to maintain the sterility of the product. For example, the

Fig. 1 Routes of parenteral administration. The following represent the most commonly used routes of administration for parenteral products: 1) intraperitoneal, 2) intravenous, 3) intramuscular, 4) subcutaneous, and 5) intradermal.

type of glass to be used in a specific parenteral drug product is indicated in the monograph. The types of packaging and containers for SVPs and LVPs will be discussed later in this article.

A SVP product is available for most of the major therapeutic classes of drug. It is often desirable for a manufacturer to provide both an oral and parenteral dosage form for a specific drug product. A “drug injection” is a liquid preparation that is composed of drug substances and or solutions. A “drug for injection” is a dry solid that upon the addition of a suitable vehicle (usually a vehicle in which the drug is stable and soluble) provides a solution that conforms to the requirements for an injection. Drugs for injection are often lyophilized or freeze-dried to assist in the reconstitution of the solid. A “drug injectable emulsion” is a liquid preparation of a drug or drug substances dissolved in a suitable emulsion vehicle. A

“drug injectable suspension” is a liquid preparation of solids suspended in a suitable vehicle. A “drug for injectable suspension” is a dry solid (often lyophilized) that is intended, upon the addition of a suitable vehicle, to yield a preparation that in all aspects meets the requirements for an injectable suspension.

LVPs are often administered via intravenous infusion in a large single-dose container. The therapeutic goal of these products is to provide electrolytes, body fluids, and nutrition. These solutions may or may not be isotonic with blood depending upon the concentration of the components, which include sodium chloride, dextrose, mannitol, Ringers (sodium, potassium, calcium, and chloride) and Lactated Ringers (calcium, potassium, sodium, and lactate), sodium bicarbonate, ammonium chloride, sodium lactate, fructose, alcohol, dextran, and amino acids. Other drugs (small volume injectables) are

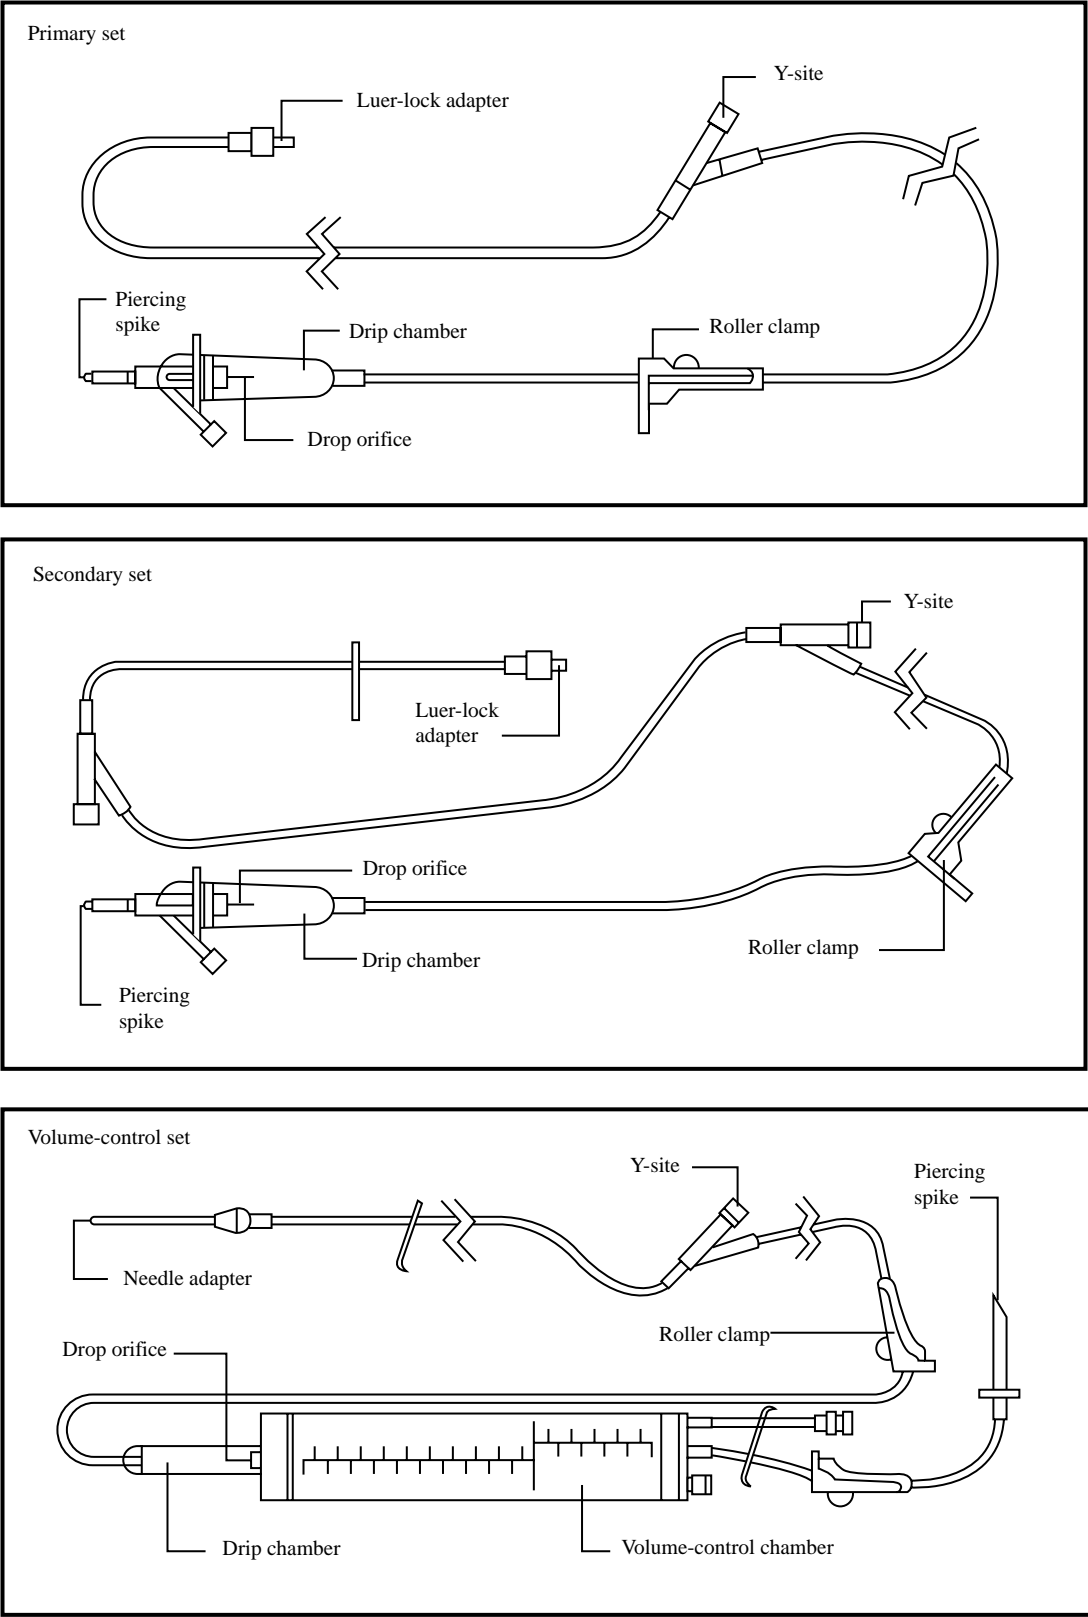

Fig. 2 Types of infusion sets used for parenteral therapy: primary, secondary, and volume-controlled infusion sets.

often combined to these LVPs, provided that these two products are compatible during the extemporaneous preparation of intravenous admixtures (discussed later).

COMPONENTS OF PARENTERAL PRODUCTS

Parenteral products are optimized during their development to provide the requisite solubility (per the required dose), stability, and syringeability. In addition, these products must meet the desired requirements for the rate of drug release based upon the dosage form and biopharmaceutical properties. Finally, it is important that parenteral products also be evaluated for their potential to cause tissue damage and/or pain associated with the injection of the formulation. The adjuvants in parenteral products can include solvents, vehicles, cosolvents, buffers, preservatives, antioxidants, inert gases, surfactants, complexation agents, and chelating agents.

It is important to understand the various types of waters used in parenteral products. The most frequently used solvent in parenteral products is Water for Injection, USP, which is not required to be sterile but must be pyrogen-free. In contrast, Sterile Water for Injection, USP is water that has been sterilized, does not include a preservative or antimicrobial agent, is pyrogen-free, and is provided in single containers no larger than 1000 ml. The use of this product is for the reconstitution of other parenteral products, in most cases antibiotics. This product must not be given alone. Bacteriostatic Water for Injection, USP is sterile water that can contain one or more preservative or antimicrobial agent (specified on the label) and is packaged in prefilled syringes or vials that are no larger than 30 ml. It is also used in the reconstitution of SVPs. The limitation with Bacteriostatic Water for Injection, USP is the presence of the antimicrobial agent that is contraindicated in newborns. Other solvents used for parenteral formulations are Sodium Chloride Injection, USP and Bacteriostatic Sodium Chloride Injection, USP, Ringers Injection, USP, and Lactated Ringer's, USP.

Other vehicles may be added to parenteral products if the aqueous solubility is limited. However, these vehicles must be nontoxic, nonsensitizing, and nonirritating (3, 6). In addition, these solvents must be compatible with the drug and other components in the formulation. Cosolvents often used in parenteral formulations include propylene glycol, ethanol, polyethylene glycols, glycerin, and dimethylacetamide. In addition, fixed vegetable oils, such as peanut, cottonseed, sesame and castor oil, can be used; however the USP provides clear restrictions on their use in parenteral products.

Buffers can also be provided in parenteral formulations to ensure the required pH needed for solubility and/or stability considerations. Other excipients included in parenteral products are preservatives (e.g., benzyl alcohol, *p*-hydroxybenzoate esters, and phenol), antioxidants (e.g., ascorbic acid, sodium bisulfite, sodium metabisulfite, cysteine, and butyl hydroxy anisole), surfactants (e.g., polyoxyethylene sorbitan monooleate), and emulsifying agents (e.g., polysorbates). An inert gas (such as nitrogen) can also be used to enhance drug stability. Stability and solubility can also be enhanced by the addition of complexation and chelating agents such as the ethylenediaminetetraacetic acid salts. For a more detailed list of approved excipients in parenteral products, the reader should consult the monographs within the USP.

PARENTERAL PACKAGING

In general, all parenteral products must be manufactured under strict, current good manufacturing processes (cGMP) to ensure the final product is sterile and pyrogen-free. Sterilization is defined as the complete destruction of all living organisms or their spores or the complete removal from the product (6). Pharmaceutical products can be sterilized by steam sterilization, dry-heat sterilization, filtration sterilization, gas sterilization, and ionizing-radiation sterilization. The USP provides monographs and standards for biological indicators required to test the validity of the sterilization process. These products must also be tested for pyrogens—fever-producing substances that arise from microbial contamination most likely thought to be endotoxins or lipopolysaccharide in the bacterial outer cell membrane.

Injections are provided in either multiple-dose containers or single-dose containers. A multiple-dose container is often a vial that will allow the withdrawal of successive portions of the contents without a change in the strength of the product and while maintaining the sterility. A single-dose product is intended for a single parenteral administration. These products can be an ampul, vial, or a syringe. For some drugs, there are specific double-chambered vials that contain the reconstitution solvent and the powdered drug (e.g., Mix-O-Vial—to be discussed later). Types I, II, and III glass are required for parenteral products and are specified in the individual monograph for a given drug.

Ampuls are utilized for a single dose and, as such, do not require a preservative. However, in many cases, the manufacturer will include a preservative, as the drug formulation is the same for both the ampul and

multiple-dose vial. The disadvantages of ampuls are that these containers become contaminated with glass particles when opened and require the use of a syringe to remove the drug solution. A filter needle must be used sometime during the withdrawal of the solution or delivery of the drug solution to a flexible bag or other intravenous solution to ensure the glass is removed from the solution. Ampuls are opened via breaking the neck at a prescored position.

Vials can be used for single or multiple doses. The glass containers are sealed with rubber closures that permit the withdrawal of the drug solution via a syringe. The disadvantage of these systems is associated with ensuring that the drug solution is compatible with the rubber closure. Furthermore, when utilizing vials in the extemporaneous preparation of sterile intravenous admixtures, the health care practitioner must minimize the potential of coring during the introduction of the needle through the rubber seal. Furthermore, there is always the concern of contamination of the solution with repeated withdrawals. The potential for contamination can be minimized by the use of single-dose vials.

Parenteral solutions can also be packaged in syringe dosage forms for a single-dose use. As such, they can be considered a type of convenience container (to be discussed later). The syringe and needle are sterile until opened. They are ideal for emergency situations or the home health care environment.

LVPs are usually provided in glass containers, flexible plastic bags, or semirigid containers. These systems are also classified as open systems (nonvacuum) and closed systems (vacuum). The largest manufacturers of LVPs are Abbott Laboratories, Baxter Healthcare Corporation, and B. Braun.

Glass containers are sealed with a thick rubber disk and a target in the center for the piercing spike. Glass bottles can be either vented with a plastic venting tube or nonvented, thereby requiring either a nonvented administration set or a vented administration set, respectively. The advantages of glass containers for parenterals are that they are easy to sterilize, can be accurately read, and are generally inert and less susceptible to incompatibilities with drugs or leaching of components compared to the plastic flexible intravenous bags. The disadvantage of glass is associated with handling the glass bottles and the potential for breakage (10).

Plastic intravenous fluid containers were first introduced due to the need to start intravenous therapy while transporting soldiers from the battlefield or triage area to the hospitals. These containers are flexible due to the presence of plasticizers, with the bags being composed of polyvinyl chloride. In contrast, semirigid containers are often composed of polyolefin. Some representative shapes

of these various types of containers are shown in Fig. 3. The most common manufacturers of intravenous solutions are Abbott Laboratories—Lifecare, Baxter Healthcare—Viaflex, and B. Braun Medical—Excel. The major advantages of plastic flexible bag systems for parenterals are that they do not require the use of a vented administration set as they collapse when empty, and they are less susceptible to breakage. It is also easier to store and transport these bags. The difficulties with these flexible plastic bags for infusions solutions are the potential for incompatibilities of the drug substance with the components in the bag (see later), the potential for the bag to get perforated during its use, thus compromising the sterility of the solution, and the difficulty in reading the volume remaining in the bag. One major concern with the use of flexible plastic bags is the potential for the drug compound to leach out the plasticizers from the systems. Semirigid containers are similar to flexible plastic containers in that they are lightweight and nonbreakable and can be easily transported and stored. These containers are less likely to be perforated during their use. More importantly, these containers do not contain plasticizers and, as such, may be more compatible with drug substances. The disadvantages are related to their similar properties to glass containers, in that they require venting, can be more susceptible to cracking upon extreme changes in temperature, should not be frozen, and do not adapt well for ambulatory care.

CONVENIENCE AND NEEDLELESS SYSTEMS

Whereas the compounding and administration of parenteral products and intravenous admixtures continues to be a vital and important component in the care of hospitalized and home health care patients, there is continued interest in easing the preparation, storage, and administration of these products with respect to controlling contamination of the finished product and protecting the health care providers from needlestick injuries. It is estimated that more than 750,000 needlestick injuries occur every year. Commonly used convenience and/or needleless systems include premixes, bags, and vial systems (e.g., Add-Vantage and Mini-Bag Plus[®]), prefilled syringe systems (Carpject[®]—Abbott and Tubex[®]—Wyeth-Ayerst) and double-chambered vial systems (Mix-O-Vial—Pharmacia-Upjohn and Redi-Vial[®]—Lilly).

For drugs with suitable stability in intravenous solutions, premixes provide an alternative to the

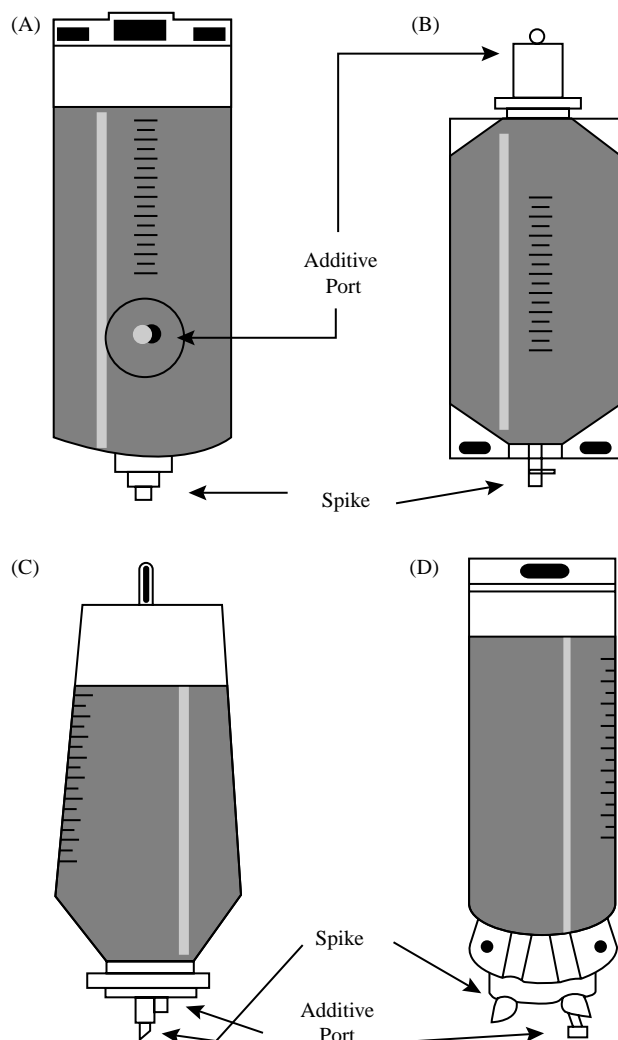

Fig. 3 Types of large volume parenterals. These represent the various types of flexible intravenous bag systems: (A) Lifecare[®] by Abbott Laboratories, (B) Representative vial and flexible IV bag system, such as the Add-Vantage[®]—Abbott Laboratories or Mini-Bag Plus System[®]—Baxter Healthcare, (C) Excel[®]—B. Braun Medical, and (D) Viaflex[®]—Baxter Healthcare. These bags contain either polyvinyl chloride (Lifecare or Viaflex) or polyolefin (Excel).

extemporaneous compounding of admixtures. These products are ready to administer, reduce the chance for a medication error, reduce the potential for infection, and decrease the chance for needlestick injuries. In addition, there is an advantage in using these products with respect to the shelf-life of the product. The stability and storage requirements for each product is provided by the manufacturer. For example, the FirstChoice[®] Premix products (Abbott) in the overwrap have a shelf-life of, typically, 18 months, whereas those products in which the

overwrap has been removed and which are stored at room temperature can be stable for up to 30 days, provided no additional drugs or additives have been added to the product. The diluents in these premix products include 0.45 or 0.9% sodium chloride, 5% dextrose, water for injection, Lactated Ringers, and combinations of these diluents in volumes ranging from 50 to 1000 ml in plastic or glass containers. Drug classes that are currently formulated as premixes include amino acids, dextrans, electrolytes, cardiovascular, anti-infectives, analgesics, and gastrointestinal and respiratory compounds.

The Add-Vantage[®] system (Abbott Laboratories) and the Mini-Bag[®] Plus system (Baxter Healthcare) are needleless drug delivery systems composed of a drug-containing vial and a diluent in a flexible plastic intravenous bag. A schematic of these type of systems is shown in Fig. 3B. The drug in the vial comes in contact with the diluent, followed by the drug being transferred back into the bag with the vial still attached; this system can then be attached directly to the infusion equipment. In the Add-Vantage system[®], there are specialized vials and intravenous bags and it is necessary for the health care professional to activate the system by removing the vial stopper, thus allowing the diluent to enter the vial. The Mini-Bag Plus[®] system is designed to allow the simple reconstitution of standard 20 mm powdered drug vials. The Monovial Safety Guard[®] (Becton, Dickinson and Company) is an integrated, self-contained system that allows the transfer of a reconstitution solution from a flexible intravenous bag or vial into a drug-containing vial, and it is only available for a limited number of drugs.

As such, the advantages of these systems are that the product can be easily stored and quickly prepared without the need for calculations, specialized equipment (such as laminar airflow hoods) or needles and syringes. They also allow for a quicker turnaround time for the first dose. These products enhance safety for both the patient, by reducing the chance for medication errors (e.g., the wrong drug added to the vial, the incorrect amount of drug to be added to the bag, or a product being incorrectly labeled), and for the health care practitioner, by minimizing the chance for a needlestick injury. In addition, these products can help to reduce costs associated with unused doses because the unwrapped products can be redistributed for short periods of time. At present, a variety of therapeutic classes of drugs from anti-infectives to cardiovascular agents to pain management at various doses are available for reconstitution in bags containing 0.9 or 0.45% sodium chloride or 5% dextrose in 50- to 250- ml bags.

Prefilled syringes (Carpject[®]—Abbott and Tubex[®]—Wyeth-Ayerst) are composed of drug solutions placed in a

syringe with a needle and needleless systems. The advantages of these systems are the convenience associated with a standard dose, less chance for medication error associated with extemporaneous compounding of these syringes, usefulness in emergency situations, and ease of storage. The needle and syringe are sterile until opened. Prefilled syringes are available for drugs ranging from anti-infectives, analgesics, and antipsychotics to antiemetics.

Doubled-chambered vials are advantageous in that the reconstitution solution is separated from the drug until desired by the health care practitioner. The Mix-O-Vial[®] (Pharmacia-Upjohn) system is a combination of a powdered or lyophilized drug in a lower container and an appropriate diluent with a preservative and other active ingredients in an upper container. Following removal of the dust cover and upon pressure on the top plunger, the solution comes in contact with the drug and the vial is shaken until a solution is obtained. The upper plunger can then be swabbed with a disinfectant and the appropriate volume of drug removed with a needle as in the standard preparation of an intravenous admixture using a vial.

With an increased interest in eliminating needlestick injuries associated with parenteral drug administration in health care workers, needleless systems are becoming more common in patient care. For example, the Interlink[®] System (Baxter) is designed for needleless access during intravenous therapy. These types of products are available for injection sites, Y-sites, vial adapters, infusion and vein access, syringe products and catheter extension sets. Other needleless catheters and infusion sites include the Introcan[®] Safety IV catheter and the Sifesite[®] injection caps (B. Braun).

NEEDLELESS INJECTION

The concept of needleless injection is not a new one and has been thought about since the 1940s. Current products utilize either spring action or compressed gas (e.g., helium or carbon dioxide) as a propellant to deliver a drug through the skin. These needleless systems offer several advantages. The first potential advantage is reduced pain and anxiety, an advantage for use in children. The second advantage is that needleless injection causes less tissue damage than conventional needles (12). Finally, a needleless system results in a diffuse pattern of exposure and, therefore, increases surface area and absorption rate (12). The main disadvantage of this system is unreliability in reference to pain and discomfort and skin characteristics

that can influence the amount of drug entering the body (12). This system has been used to administer vaccines, insulin (12), and drugs for topical applications (e.g., penile erectile dysfunction) (13) and as a means to deliver DNA for gene therapy (14).

EXTEMPORANEOUS COMPOUNDING OF PARENTERAL PRODUCTS

Whereas the presence of the various convenience parenteral products has assisted health care practitioners in safely and accurately delivering drugs to the patients, the extemporaneous compounding of parenteral products continues to be an important component in institutional settings and home health care (3, 5, 15). Parenteral intravenous admixtures include the withdrawing of the drug solution from an ampul(s) or vial(s) and placing it into various large volume solutions, syringe dosage forms for patients, total parenteral nutrition solutions and cassettes, or other delivery systems for home health care patients. The American Society of Health-System Pharmacists, the National Association of Boards of Pharmacy, and the USP provide practitioners with useful technical assistance bulletins, rules, and standards for the preparation of parenteral products (13). The concerns associated with the extemporaneous preparation of parenteral products are maintaining sterility of the products through proper aseptic techniques, calculating and providing the correct dosage, preventing or reducing drug–drug, drug–solution, or drug–container incompatibilities during the preparation or administration of the product, and maintaining and providing drug stability and quality control.

The majority of extemporaneous parenteral products are prepared by pharmacists working in hospitals, home health care, or long-term care facilities. These products must be prepared using aseptic technique and using the appropriate supplies (e.g., syringes, needles, and filter needles, and caps) and equipment (Class 100 laminar airflow hoods enclosed within a class 10,000 clean room). Aseptic technique which differs from sterilization, is a process by which an individual can manipulate sterile products and containers to prevent microbial contamination. Pharmacists and other personnel involved in the extemporaneous preparation of parenteral products require special knowledge and training and should receive additional training and education on a routine basis to ensure proper aseptic techniques are being followed consistently. In addition, these individuals must be able to perform the required calculations (e.g., dosing,

milliequivalents, milliosmoles, and powder volume) needed to prepare intravenous admixtures. Equally important to the safe preparation of intravenous admixtures is an understanding of general principles and concepts related to drug and solution or container incompatibilities and to drug stability and also specific knowledge as to whether a specific drug is compatible or stable with another drug, solution, or container. For example, general and specific information on intravenous admixture incompatibilities can be found in books such as *Handbook on Injectable Drugs* (16, 17) and *King Guide to Parenteral Admixtures* (18) and in primary literature sources such as the *American Journal of Health-System Pharmacy* and the *International Journal of Pharmaceutical Compounding*.

INFUSION PUMPS AND DEVICES

Infusion pumps and devices are an essential component to the delivery of parenteral drugs, particularly those given by the intravenous route. For drugs that are administered via intravenous infusion, there are two forces that control fluid flow: 1) the pressure of an active force of the liquid that can be generated via gravity flow (*viz.*, hydrostatic pressure) or mechanically via a positive pressure pump and 2) resistance, or an opposing force, that is generated via the infusion sets, a vascular access device and/or blood vessels. The maximum flow rate will depend upon the ratio of the change in pressure exerted by the liquid to that of the change in resistance.

An infusion control device (ICD) is a device that maintains a constant infusion rate in a gravity flow system (controller) or via a positive pressure pump. A positive pressure pump is a device that provides mechanical pressure (2–12 psi) to overcome the resistance to flow in the vessels. The types of positive pressure pumps are categorized according to how they deliver the solution and their degree of precision in the flow rate. Positive pressure pumps include peristaltic pumps, cassette pumps, syringe pumps, nonelectric or disposable pumps, and patient-controlled analgesic pumps (PCA). Syringe pumps are usually the most accurate pumps, with flow variances at 2% or less. Nonelectric or disposable syringe and PCA pumps are useful for ambulatory care. PCA pumps are very useful for the parenteral administration of analgesics (*viz.*, morphine) and can be easily programmed to deliver bolus doses and provide a dosing history. Nonelectric or disposable pumps (*e.g.*, Homepump®—I-Flow Corporation, Readymed®—Alaris Medical Systems, and Smart-Dose®—ProMed) are lightweight, and the solution is

delivered based upon a vacuum or through the generation of a gas in the system. A recent consensus development conference on the safety, cost, simplicity of use, and training of intravenous drug delivery systems, focusing on acute care and nonelectronic devices, reviewed the use of manufacturer-prepared (*e.g.*, premixed or frozen products), point-of-care activated systems (manufacturer-prepared products that require the drug and diluent to be mixed at the point of care), pharmacy-based intravenous admixture, intravenous push medications in prepared or premade syringes, augmented iv push systems (syringe pumps), and volume control chambers (19). Manufacturer-prepared products, point-of-care activated products, and pharmacy-based intravenous admixture programs were recommended as being superior intravenous drug delivery systems, with the manufactured products being considered the safest systems due to the quality assurance in the preparation of these products.

FUTURE PARENTERAL DOSAGE FORMS

Current research is leading to newer types of parenteral dosage forms that will be useful for both immediate and sustained drug delivery, for systemic and targeted drug delivery, and for the delivery of small molecules and macromolecules (*e.g.*, proteins, peptides, and DNA). There has been an increased interest in developing a wide variety of particulate drug delivery systems for parenteral products, which have included liposomes or other phospholipid vesicles, microspheres, microcapsules, nanoparticles, or microemulsions (20–23). The development of new biomaterials, such as the linear and branched biodegradable polyesters, has increased the interest in the development of these systems for microsphere formulations for parenteral drugs (24, 25). An advantage is that drug molecules can be incorporated into these particulate carriers, and, as such, the rate of drug release can be modified, cellular uptake can be facilitated, or the degree of tissue damage or pain can be reduced.

Microemulsions, defined as clear solutions obtained by triturating normal coarse oil-in-water emulsions with a medium chain alcohol and composed of the nonpolar phase, surfactant and cosurfactant, appear to be potentially useful for parenteral administration, as these are clear and stable formulations that are able to be filtered and might be suitable for intravenous administration (21, 22). In addition, other researchers are investigating *in situ* forming gel or implants that can be easily injected intramuscularly or subcutaneously and that result in the formation of a depot at the site of injection with the

potential to modify or extend the release of the drug or macromolecule (25–27).

CONCLUSIONS

Parenteral products will continue to play a vital role in the treatment of patients when the oral route is contraindicated, when it is necessary to carefully control drug blood levels in response to therapeutic effects, when a prolonged therapeutic effect is needed through a long-acting injectable, or when a drug effect is to be targeted to a specific tissue or organ, to name a few instances. Advances in the technology required for the administration of parenteral dosage forms in the last 100 years have expanded their clinical uses for in-patient and out-patient settings. In addition, there is improved convenience and safety for the health care providers who prepare and administer these products. It seems likely that more parenteral dosage forms will become available in the marketplace in response to the compounds being developed through biotechnology.

DRUG DELIVERY—BUCCAL ROUTE

James C. McElnay
Carmel M. Hughes

The Queen's University of Belfast, Belfast, United Kingdom

INTRODUCTION

A drug can be administered via many different routes to produce a systemic pharmacologic effect. The most common method of drug administration is via the *peroral* route, in which the drug is swallowed and enters the systemic circulation primarily through the membranes of the small intestine. Although this type of drug administration is commonly termed *oral*, *peroral* is a better term because *oral* administration more accurately describes drug absorption from the mouth itself. The mouth is lined with a mucous membrane and among the least known of its functions is its capability of serving as a site for the absorption of drugs (1). In general, drugs penetrate the mucous membrane by simple diffusion and are carried in the blood, which richly supplies the salivary glands and their ducts, into the systemic circulation via the jugular vein. Active transport, pinocytosis, and passage through aqueous pores usually play only insignificant roles in moving drugs across the oral mucosa (2).

The administration of drugs by the buccal route has several main advantages over peroral administration, including the following:

1. The drug is not subjected to the destructive acidic environment of the stomach.
2. Therapeutic serum concentrations of the drug can be achieved more rapidly.
3. The drug enters the general circulation without first passing through the liver.

This last phenomenon is important for drugs that are highly metabolized during their first passage through the liver. This metabolism (governed by the hepatic extraction ratio) can lead to a dramatic reduction in the amount of drug available systemically from a given peroral dose but is avoided by buccal absorption.

Two sites within the buccal cavity have been used for drug administration. Using the sublingual route, as for glyceryl trinitrate (GTN), the medicament is placed under the tongue, usually in the form of a rapidly dissolving tablet. The second anatomic site for drug administration is between the cheek and gingiva. Although this second application site is itself known as *buccal absorption*, the

absorption from all areas within the buccal or oral cavity are considered in this article.

Of the range of pharmaceutical preparations available for administration into the oral cavity, the most popular form is that of a rapidly dissolving tablet that releases its drug contents for absorption across the oral mucosa. Alternatively, a tablet or capsule can be chewed to release its contents. This latter method is less successful because mastication tends to produce a large volume of saliva that increases the probability of premature swallowing. The same problem occurs in the administration of drug in the form of a chewing gum.

The aim of the present article is to review the published literature on the absorption of drugs through the oral mucosa. Special attention is given to the prevention of presystemic metabolism via drug administration by the buccal and sublingual routes. Consideration is also given to the types of pharmaceutical preparations that are commercially available for drug administration into the mouth. Before progressing to drug absorption, however, the structure and blood supply of the oral mucosa are discussed because of the important role they play in the transfer of drugs from the mouth into the systemic circulation.

STRUCTURE AND SECRETIONS OF THE ORAL MUCOSA

Epithelial Lining

The major function of the oral epithelium is to provide a protective surface layer between the oral environment and the deeper tissues. The oral epithelium has a squamous epithelium of tightly packed cells that form distinct layers by a process of maturation from the deeper layers to the surface (3). The pattern of maturation differs in different regions of the oral mucosa due to the variation in the specific function of the tissues. The surface layer of the hard palate and tongue forms keratin to yield a tough, nonflexible epithelial surface resistant to abrasion, but the epithelium of the cheek, floor of the mouth, and soft palate is nonkeratinized and facilitates distensibility. The major features of the keratinized and non-keratinized oral

epithelium have been extensively investigated by Squier and Rooney (4). Together with the presence or absence of keratin, the second main feature likely to influence regional differences in drug absorption is the epithelial thickness. This varies in different regions of the mouth: the hard palate, buccal mucosa, lip mucosa, and floor of the mouth have been found to have thicknesses of 100–120 μm , 500–600 μm , 500–600 μm , and 100–200 μm , respectively (5, 6).

Secretion of Saliva

In addition to the protective function afforded by the oral mucosa, it also has the ability to maintain a moist surface, which enhances permeability of the membrane to drugs (3). Although the mucous membrane lining in the mouth contains many minute glands called *buccal glands*, which pour their secretions into the mouth, the chief secretion is supplied by three pairs of glands, namely, the *parotid* (under and in front of the ear), the *submaxillary* (below the jaw), and the *sublingual* (under the tongue) glands. Blood is richly supplied to the salivary glands and their ducts by branches of the external carotid artery and afterwards, travelling through the many branch arteries and capillaries, returns to the systemic circulation via the jugular veins (1). The presence of saliva in the mouth is important to drug absorption for two main reasons:

1. Drug permeation across moist (mucous) membranes occurs much more readily than across nonmucous membranes.
2. Drugs are commonly administered to the mouth in the clinical setting in a solid form. The drug must, therefore, first dissolve in saliva before it can be absorbed across the oral mucosa; that is, the drug cannot be absorbed directly from a tablet.

VASCULAR SYSTEM OF THE ORAL MUCOSA

The vascular system and blood supply to the oral mucosa have been clearly described by Stablein and Meyer (7). Netter's excellent drawings of the blood supply to the mouth and pharynx, venous drainage of the mouth and pharynx, and lymphatic drainage of the mouth and pharynx have been published by Ciba (8). This latter publication also includes definitive documentation of the blood supply and drainage from the mouth.

The blood supply to the mouth is delivered principally via the external carotid artery. The maxillary artery is the major branch, and the two minor branches are the lingual

and facial arteries. The lingual artery and its branch, the sublingual artery, supply the tongue, the floor of the mouth, and the gingiva, and the facial artery supplies blood to the lips and soft palate. The maxillary artery supplies the main cheek, hard palate, and the maxillary and mandibular gingiva (7, 9). The internal jugular vein eventually receives almost all of the blood derived from the mouth and pharynx (8). Drugs diffusing across the membranes have easy access to the systemic circulation via the internal jugular vein.

FACTORS INFLUENCING DRUG ABSORPTION FROM THE ORAL CAVITY

Because the oral mucosa is a highly vascular tissue, the two main factors that influence drug absorption from the mouth are the permeability of the oral mucosa to the drug and the physicochemical characteristics of the drug that is presented at the site of absorption.

Permeability of the Oral Mucosa to Drugs

The lipid membranes of the oral mucosa are resistant to the passage of large macromolecules; however, small un-ionized molecules tend to cross the membrane with relative ease. This passage is in either direction, and indeed passage of drugs from the circulation into the mouth can be used in therapeutic drug monitoring by measuring drug concentrations in saliva. The permeability of the oral mucosa has been comprehensively reviewed by Siegel (10).

Mechanisms involved in drug absorption across the oral mucosa

The mechanisms by which drugs cross biologic lipid membranes are passive diffusion, facilitated diffusion, active transport, and pinocytosis. Small, water-soluble molecules may pass through small, water-filled pores. The main mechanism involved in drug transfer across the oral mucosa, common with all regions of the gastrointestinal tract, is passive diffusion, although facilitated diffusion has also been shown to take place, primarily with nutrients. *Passive diffusion* involves the movement of a solute from a region of high concentration in the mouth to a region of low concentration within the buccal tissues. Further diffusion then takes place into the venous capillary system, with the drug eventually reaching the systemic circulation via the jugular vein. The physicochemical characteristics of a drug are very important for this diffusion process. Although passive diffusion is undoubtedly the major transport mechanism for drugs, the

Fig. 1 Schematic representation of the absorption kinetics of buccally presented drugs. (From Ref. 10)

absorption of nutrients from the mouth has been shown to involve carrier systems (*facilitated diffusion*), which lead to a more rapid absorption than the concentration gradient would promote. Such a carrier system, unlike passive diffusion, exhibits stereospecificity, and indeed the absorption of D-glucose and L-arabinose across the buccal mucosa has been shown to be stereospecific (11). The same authors also showed that the absorption of D-glucose, galactose, and 3-O-methyl-D-glucose was at least partially dependent on the presence of sodium ions in the luminal fluids. Furthermore, the transport of D-glucose was inhibited by galactose and 3-O-methyl-D-glucose, suggesting at least one common carrier system. Similarly, Kurosaki et al. (12) demonstrated that the absorption of cefadroxil (a cephalosporin antibiotic) from the human oral cavity occurs through a carrier-mediated mechanism; this absorption was inhibited by the presence of cephalexin, which shares a common carrier-mediated process with cefadroxil in the small intestine of rat.

Membrane storage during buccal absorption of drugs

The absorption of a drug from the mouth is not synonymous with drug entry into the systemic circulation. Instead, the drug appears to be stored in the buccal membranes, sometimes known as the membrane reservoir effect (13). Due to this phenomenon, buccal partitioning has been suggested as a more accurate term to describe the diffusion of drugs across the oral mucosa (14). Although several authors have devised schematic representations of the kinetics of oral drug absorption (Fig. 1) and (1, 14) the mucosal constituents responsible for drug binding have not been identified.

Regional differences in mucosal permeability

The epithelial lining of the mouth differs in both composition (keratinized and nonkeratinized) and

thickness in different regions of the mouth. Therefore, drug absorption may vary from different oral sites. This site-dependent absorption has been shown to take place by Pimlott and Addy (15), who measured the absorption of isosorbide dinitrate into the systemic circulation after applying tablets to the buccal, palatal, or sublingual mucosa in six healthy volunteer subjects. Serum levels of drug were detected from the buccal and sublingual sites after 1 min. The drug concentration progressively increased, peaking at 5 min, and then decreased during the 30-min sampling period. At most of the time periods, serum concentrations were higher from sublingual sites than from buccal sites (Fig. 2). The drug was not detected in the serum of any subject after application to the palatal mucosa. These authors concluded that the keratinized layer of the oral mucosa may be an important barrier to drug absorption because the palatal epithelium is keratinized, but the buccal and sublingual mucosa are not (16). Absorption across the sublingual epithelium is likely to be greater than across the buccal epithelium because the former is thinner and is immersed in a larger volume of saliva.

Rapid absorption from the sublingual mucosa was also demonstrated through work by Al-Furaih et al. (17), who reported that sublingual administration of captopril led to a more rapid attainment of plasma captopril concentrations and had a more rapid pharmacological effect (i.e., lower systolic blood pressure) compared to peroral administration of the drug.

Physicochemical Characteristics of the Drug

Various experimental techniques have demonstrated that cell membranes have a large lipid component (18), and most drugs cross such membranes by simple passive diffusion. In order to cross these lipid membranes, a drug should be in the lipid-soluble or un-ionized form and also

Fig. 2 Mean plasma isosorbide dinitrate concentrations after application of isosorbide dinitrate (5 mg) to the buccal and sublingual mucosa in six healthy male volunteer subjects. (Redrawn from Ref. 15.)

be in solution. The various physicochemical characteristics of the drug are, therefore, of paramount importance as far as drug penetration across the oral mucosa is concerned.

Molecular weight

In general, molecules penetrate the oral mucosa more rapidly than ions, and smaller molecules penetrate more rapidly than larger molecules. However, this rule is not absolute because dextrans with a molecular weight of up to 70,000 cross keratinized rabbit oral mucosa (19), but horseradish peroxidase (molecular weight 40,000) does not (20). High-molecular-weight mucopolysaccharides such as heparin are not well absorbed (21), although inclusion of penetration enhancers in some insulin formulations have improved bioavailability (22).

Degree of ionization

The average pH of saliva is 6.4. Because the un-ionized form of a drug is the lipid-soluble-diffusible form, the pK_a of the drug plays an important role in its absorption across the lipid membranes of the oral mucosa. The degree of ionization of a drug at a specified pH can be calculated using the Henderson–Hasselbalch equation as follows:

For an acid :

$$pH = pK_a + \log_{10} \frac{[\text{un-ionized species}]}{[\text{ionized species}]}$$

For a base :

$$pH = pK_a + \log$$

The importance of pH on drug absorption from the mouth has been extensively studied using the buccal absorption model, in which loss of drug from buffered drug solutions placed in the mouth is monitored (23). The influence of pH on the absorption of the weak base chloroquine and of the weak acid phenobarbitone is shown in Fig. 3 (24).

However, pH does not always influence the rate or extent of absorption. For example, McElnay et al. (25) found that captopril pharmacodynamic parameters (blood pressure, heart rate, and plasma renin activity) did not differ significantly between buffered and unbuffered sublingual administration, suggesting that manipulation of pH had little effect. It was, therefore, proposed that a mechanism other than passive diffusion was involved in the buccal absorption of this drug.

Although many studies illustrate the importance of ionization on drug absorption, the pH of saliva is relatively constant, and in the absence of a buffer, the pK_a of the drug plays the deciding role as to the state of drug ionization.

Fig. 3 The influence of pH on the absorption of the weak acid phenobarbitone and the weak base chloroquine from the buccal cavity in three healthy volunteer subjects. (Redrawn from Ref. 24.)

Also, due to the relatively large surface area available for absorption and to the maintenance of an equilibrium between ionized and un-ionized drug, only a small percentage of drug has to be present in the un-ionized form before significant absorption can take place.

Lipid solubility

Although the undissociated (un-ionized) form of a drug has the higher lipid solubility, the un-ionized moieties themselves have differing lipid solubilities. A common way of assessing the lipid solubility of a drug is to measure its oil–water partition coefficient. As with pH, buccal absorption has been shown to be positively correlated with a drug's oil–water partition coefficient. Beckett and Moffat (26), for example, found a correlation of partition coefficients in *n*-heptane/aqueous systems with buccal absorption data for a series of amines and acids when the degree of ionization was held constant.

In conclusion, to penetrate the oral mucosa to a significant degree, a drug should have a relatively low molecular weight and exhibit biphasic solubility patterns, that is, be soluble in both the aqueous salivary fluid and the lipid membrane barrier to penetration. A significant amount of the drug should be un-ionized at salivary pH, and the drug should also not bind strongly to the oral mucosa.

BUCCAL ADMINISTRATION AS A METHOD OF PREVENTING PRESYSTEMIC METABOLISM

The systemic availability of a drug is a measure of the fraction of the administered amount of drug that is absorbed into the general circulation in an unchanged form from its site of administration. Disregarding pharmaceutical reasons (e.g., poor tablet disintegration) and inappropriate physicochemical properties of the drug, the two main reasons for poor bioavailability after peroral administration are drug destruction by stomach acid and drug modification by metabolic enzyme systems prior to its entry into the systemic circulation. The principal organs involved in presystemic elimination are the gut wall, the liver, and the lung (27). Drug metabolism of this type is known as *first-pass* metabolism. A number of drugs have high affinities for the enzyme systems in these organs and are, therefore, highly extracted during their flow through the organs. These drugs, which are said to have a *high extraction ratio* (Fig. 4), include propranolol, terbutaline, levodopa, imipramine, aspirin, morphine, pentazocine, nitroglycerin, lignocaine, hydralazine, verapamil, and methyldopa. The main metabolizing organ in the body is the liver. Because blood draining from the gut via the portal vein must pass

Fig. 4 Diagrammatic representation of the extraction ratio of a drug. The extraction ratio is a measure of the tendency of a drug to be removed from the blood during its passage through an organ such as the liver. In the diagram, C_A is the arterial drug concentration and C_V is the venous drug concentration.

through the liver prior to entry into the general circulation, the total drug absorbed from the gut must pass through the liver before it can reach its site of action. Once the drug has entered the systemic circulation, it is distributed to other areas of the body (depending on its volume distribution); although the extraction ratio remains constant, the proportion of the total drug in the body that is metabolized on subsequent passes through the liver is reduced due to a lowered drug concentration in the plasma after distribution has taken place. The liver receives only 20% of the cardiac output (as compared with 100% from the portal vein), which also protects the drug that has already been absorbed from the metabolic systems of this organ. Presystemic elimination can, therefore, be avoided by choosing a site of administration from which the drug enters the systemic circulation directly, without first passing through the liver, lung, or gut wall. Because blood draining from the oral cavity enters the general circulation via the internal jugular vein, oral administration by the buccal or sublingual routes provides a useful strategy for improving bioavailability of drugs that are susceptible to extensive first-pass metabolism. A high first-pass effect does not, however, mean that drugs with a high extraction ratio cannot be given perorally. If a sufficient dose of the drug is given, an adequate amount of drug (to produce the required therapeutic effect) often remains intact during its first passage through the liver. Also, a high peroral dose of drug or, indeed, serum levels of the drug from previous doses may saturate the high-affinity metabolizing systems in the liver and, thereby, decrease the first-pass effect and increase bioavailability. With some drugs, moreover, the metabolites themselves may have good pharmacologic activity.

DRUGS AND PHARMACEUTICAL FORMULATIONS FOR ADMINISTRATION BY THE BUCCAL AND SUBLINGUAL ROUTES

Although the data produced using the buccal partitioning model of drug absorption (23) have shown that numerous

drugs are absorbed efficiently from the oral cavity, few drugs have been assessed clinically after administration by this route, and not all drugs that have given encouraging clinical data have specific formulations available for intraoral administration. Drugs within the cardiovascular and strong analgesic pharmacologic classes have received the most attention.

Cardiovascular Drugs

Glyceryl trinitrate (GTN)

This vasodilator has been used for over 100 years in the treatment of angina pectoris, and today, many clinicians consider it the most effective drug despite exhaustive efforts to find alternatives. It is also used in the treatment of congestive heart failure. This drug is rapidly absorbed from the mouth, with much of the drug bypassing the liver. The liver has a high metabolic capacity for organic nitrates by virtue of the enzyme glutathione reductase (28). Sublingual administration of GTN is the most appropriate action to alleviate the pain of an acute angina attack because of its rapid action, its long-established efficacy, and its low cost (29). The traditional pharmaceutical formulation of the drug is a rapidly dissolving tablet for administration under the tongue. This approach, however, has two main disadvantages:

1. The time taken for the tablet to disintegrate and dissolve may vary from person to person. A delayed and varied onset of action may result.
2. The tablets of GTN lose significant potency after only 8 weeks of the initial opening of the manufacturer's bottle and should be discarded after that period because exposure to moisture and to the atmosphere accelerates nitrate breakdown. Heat also accelerates drug deterioration.

In an attempt to overcome the previously noted problems with the sublingual tablet formulations, GTN is now widely available in metered-dose aerosol preparations. The sprays usually contain 0.4 mg GTN per unit dose. The manufacturers suggest that 1 or 2 metered doses be sprayed on the oral mucosa (preferably under the tongue) and then the mouth should be closed.

A slightly different approach has been taken by Pharmax, the manufacturer of Suscard Buccal tablets. Instead of the traditional 300-, 500-, and 600- μ g sublingual tablets, the Pharmax tablets contain 1, 2, 3, or 5 mg of GTN and are placed between the upper lip and the gum on either side of the front teeth. During the dissolution phase, the tablet softens and adheres to the

gum, after which dissolution continues in a uniform and gradual manner. Because this is a prolonged-release dosage form, the patient should not increase the tablet's dissolution rate by moving it around the mouth. The tablet should be replaced if accidentally swallowed, and the placement of successive tablets should be alternated on either side of the mouth. As well as an effective prophylactic in angina, this formulation has been shown to be effective in congestive heart failure (30).

Isosorbide dinitrate

This nitrate is also active sublingually and is a more chemically stable drug for those who require nitrates only infrequently. It is a longer-acting drug than GTN. The activity of isosorbide dinitrate may depend on the production of active metabolites, the most important of which is isosorbide 5-mononitrate. Isosorbide mononitrate is also available for angina prophylaxis, though the advantages over isosorbide dinitrate have not yet been firmly established (31). The general consensus is that the activity of the dinitrate is also longer than that of GTN Kattus et al. (32), for example, found that sublingual isosorbide dinitrate offered protection against angina for 2.5–3 h compared to 1 h relief with GTN. The finding of equal bioavailability of chewable (buccal absorption) and slow-release capsules (intestinal absorption) “infers that buccal or sublingual absorption does not circumvent the first pass effect, that presystemic metabolism occurs in the buccal mucosa, that buccal absorption is not as effective as believed or that isosorbide dinitrate is swallowed and not absorbed by the buccal mucosa. The identical pattern of metabolites after buccal and intestinal administration favours the theory that buccal absorption is slow and that isosorbide dinitrate is swallowed with the saliva in which it is dissolved” (33). Current knowledge concerning the buccal absorption route supports this theory. The main advantage of sublingual and buccal dosing may be the rapid disintegration and dissolution of the tablet in saliva. Present knowledge suggests using the drug buccally for the treatment of acute attacks of angina and using a sustained-release formulation for prophylactic purposes. Iga and Ogawa (34) demonstrated that a sustained release buccal formulation of both GTN and isosorbide dinitrate increased the bioavailability of both drugs when administered to dogs, compared to oral administration. A number of isosorbide dinitrate preparations are available for administration by the buccal or sublingual routes, the usual strengths being 5 or 10 mg. Although chewable preparations are available, the more traditional quick-disintegrating tablets predominate. Because mastication tends to increase saliva production, in order to prevent premature swallowing of the drug, the

traditional tablet type may also be preferable. Sublingual rather than buccal administration may also be preferable because higher plasma concentrations have been found in healthy volunteers when the former route was used (15). (Fig. 2)

Nifedipine

In the past, the difficulties presented in the administration of drugs in the treatment of hypertensive emergencies were largely overcome with the use of nifedipine administered sublingually (35). The onset of action was rapid, and the drug was also used sublingually for the treatment of acute attacks of angina pectoris. Presently, two types of formulation of nifedipine are available, both intended primarily for peroral administration. The sustained-release formulation is solely used perorally; however, the rapid-release capsule, which contains nifedipine in solution form, was formerly administered to the buccal cavity. However, the manufacturers now state in their literature that “nifedipine should not be used for the treatment of acute attacks of angina” as it has been associated with large variations in blood pressure and reflex tachycardia (36).

Captopril

Two studies (37, 38) have indicated the usefulness of sublingual captopril in the treatment of severe hypertension. The hypertensive patients thus treated showed a marked decrease in systolic and diastolic blood pressure, with the onset of action being 2–5 min and the peak effect at 10 min (37). Perorally administered captopril takes 1–2 h to achieve a maximal therapeutic effect (39) and, therefore, is unsuitable for the treatment of hypertensive crisis. Al-Furaih et al. (17) reported that sublingual administration of captopril (followed by plasma monitoring of drug levels) led to a more rapid attainment of plasma captopril concentrations and had a more rapid pharmacological effect (i.e., lower systolic blood pressure) compared to peroral administration of the drug as shown in Fig. 5.

Iscan et al. (40) compared a number of parameters of a specially formulated buccal bioadhesive captopril tablet with that of a conventional tablet. The buccal formulation provided controlled release of captopril with a smooth plasma level profile and a long duration of action; however, its bioavailability was 40% via the buccal route as compared to 65% following an oral dose. This was attributed to the intestinal mucosa being more permeable than the buccal mucosa, and it was concluded that further work was required to improve its bioavailability.

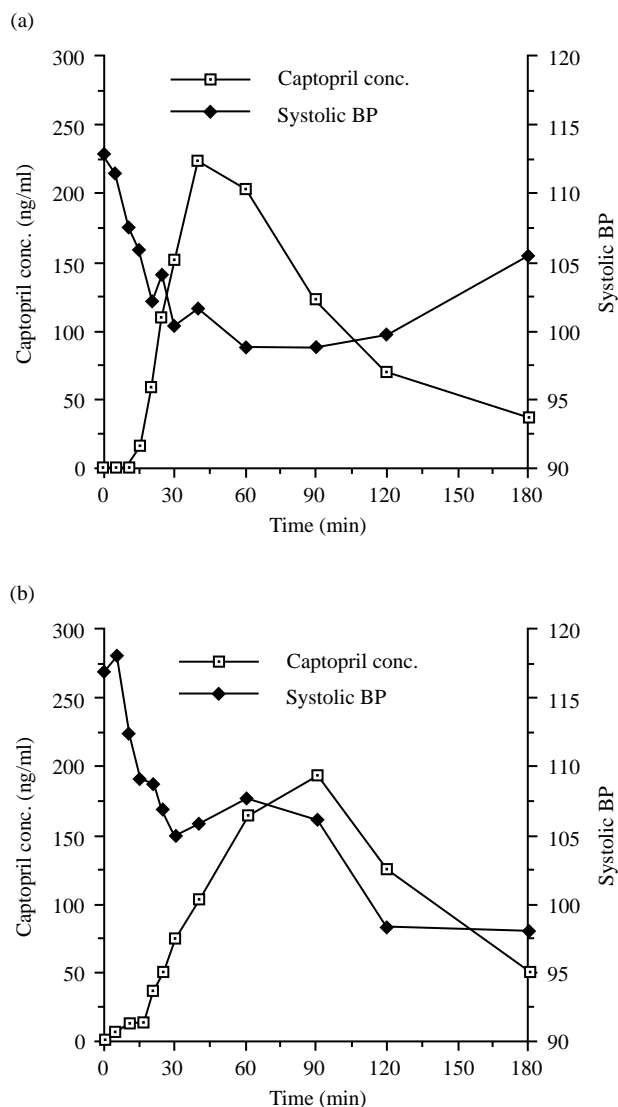

Fig. 5 Correlation over time of systolic blood pressure (◆) with plasma unchanged captopril concentration (□) after sublingual (a) and peroral (b) administration of 25 mg of captopril. (From Ref. 17.)

Analgesics

Buprenorphine

In common with other phenolic opiate analgesics, buprenorphine shows low peroral potency, suggesting a high first-pass metabolism effect; indeed, work in rats has shown this to be the case (27). Intravenous studies have estimated that the extraction ratio of buprenorphine is 85% and that peroral systemic availability is consequently expected to be 15% or less (41). Although absorption from the mouth is slow and, therefore, not as useful as parenteral

administration in the treatment of acute pain, it offers a major bioavailability advantage over the peroral route for this drug (42). If required, the patient can be given a parenteral dose of buprenorphine to achieve rapid pain relief and thereafter be maintained on sublingual drug. The drug is available as a sublingual tablet containing 200 or 400 μg of buprenorphine hydrochloride for the treatment of moderate to severe pain.

Morphine

Although not routinely given by the buccal or sublingual routes, several research studies have shown that absorption of morphine from the mouth gives rise to effective analgesia and that these routes may provide suitable alternatives to parenteral administration (43). Clinical studies have suggested that the bioavailability of morphine is 40–50% greater after buccal than intramuscular administration; as plasma morphine concentrations decline more slowly after buccal administration, buccal morphine may be associated with enhanced analgesia (44). Anlar et al. (45) administered buccoadhesive morphine sulphate tablets to six healthy volunteers, resulting in up to 30% of active drug being absorbed; this is in contrast to absolute bioavailability of a morphine sulphate solution of 23% (46). Christrup et al. (47) found that buccal delivery of morphine sulphate could be enhanced further by using ester prodrugs with higher lipophilicity than the parent drug itself.

Ketobemidone

Ketobemidone is a narcotic analgesic that has been used clinically in Scandinavia and other European countries. The mean bioavailability in humans has been reported to be approximately 35% following oral administration, but this can be substantially improved when administered by the sublingual or buccal route (48). To date, *in vitro* work has focussed on the use of the ketobemidone prodrugs (largely esters), and published results suggest that, as with morphine sulfate, buccal mucosa permeation is greatly improved (49, 50).

Flurbiprofen

Studies have suggested that this nonsteroidal anti-inflammatory drug may be useful in the treatment of periodontal disease. Manipulation of pH was shown to influence the amount of drug absorbed; an increase in pH resulted in a reduction of drug absorbed, thus resulting in a poor local effect (51). Gonzalez-Younes et al. (52) reported that the drug was tightly bound to the membrane of the tissues in the mouth.

Peptide Drugs

The oral mucosa has been cited as a route of administration for peptide drugs as a way of avoiding parenteral delivery, although permeability is low, which reduces its value as a viable option (22). However, modifications to drug formulation may offer greater success. The addition of penetration enhancers to dosage forms appears to improve bioavailability to the greatest extent, by improving the permeability of the epithelium and/or affecting the nature of the drug (53). To date, much of the experimental work has been conducted in animals.

Insulin

To achieve hypoglycemia with insulin, the traditional route of administration has been via subcutaneous injection. Peroral preparations are not feasible due to the degradation of insulin by gastric acid and enzymes. However, studies carried out in animals utilising buccal formulations have been more successful. Ritschel et al. (54) administered insulin to beagle dogs using solutions of different pHs. Bioavailability (22.3%) was maximized at pH 7.5, and the addition of penetration enhancers (bile salts) did not increase this further. Experimental work in rabbits found that in the absence of penetration enhancers, insulin solutions over a range of pHs did not show any significant hypoglycaemic response, indicating that insulin was not absorbed to a significant degree through the buccal mucosa (55).

Buserelin

This luteinizing hormone-releasing hormone has been used in the treatment of endometriosis and hormone-dependent tumors. Modes of administration have included injections, nasal sprays and subcutaneous implantations. One study, conducted in pigs, demonstrated the value of glycodeoxycholate (a penetration enhancer) in improving the bioavailability of buserelin by up to five-fold after buccal delivery (56).

α -Interferon

α -Interferon has broad antiviral and antiproliferative activity and has been used in HIV and certain forms of hepatitis. As with other peptide drugs, ways have been sought to improve the buccal delivery of α -interferon to avoid gastro-intestinal degradation and first-pass metabolism. Using a range of penetration enhancers, Stewart et al. (57) noted improved bioavailability, particularly with sodium taurocholate, in rats. As with all of the studies reviewed under the category of peptide drugs, extrapolation to the human situation should be done with caution.

Miscellaneous Drugs

Nicotine

The absorption of nicotine from chewing tobacco has been widely used for many years. Buccal absorption of nicotine is also the route of absorption for pipe and cigar smokers if the smoke is not inhaled. Nicotine replacement therapy has been used in smoking cessation strategies. Nicotine in the form of chewing gum carries no cancer risk and is a useful part of a smoking cessation strategy (58). A recent innovation has been the development of a sublingual tablet (available in 2 mg); a clinical trial has shown that this formulation is a safe form of administration (59), and patients may use one tablet every 1–2 h.

Zinc

Zinc gluconate in the form of a lozenge has been marketed for the treatment of the common cold; there has been no definitive conclusion as to whether it is effective in treating cold symptoms, although differences in study methodology may partially explain the conflicting results that have been reported (60, 61).

Midazolam

Midazolam administered buccally in solution has been shown to be rapidly absorbed and produces changes in EEG readings (62). The authors suggested that this may offer an alternative to rectal administration of diazepam in the emergency treatment of seizures.

CONCLUSIONS

The buccal cavity provides a highly vascular mucous membrane site for the administration of drugs. The epithelial lining of the oral cavity differs both in type (keratinized and nonkeratinized) and in thickness in different areas, and the differences give rise to regional variations in permeability to drugs. Although some macromolecules have been shown to cross the absorption barrier (lipid membrane), the absorption of smaller drug molecules occurs more reproducibly and rapidly. The main absorption mechanism is passive diffusion of the un-ionized (lipid-soluble) form of the drug. Facilitated diffusion has also been shown to take place with nutrients. Drugs are often stored or bound to the buccal mucosa prior to entry into the bloodstream. The blood drainage from the mouth enters the general circulation directly without first passing through the liver. This feature enhances the bioavailability of certain drugs as compared with peroral administration because first-pass metabolism is avoided.

To ensure adequate absorption from the mouth, a drug administered as a solid dosage form must exhibit *biphasic solubility*, that is, be soluble in saliva and in the lipid membranes of the buccal cavity. The major drugs currently available for buccal administration fall within the vasodilator and strong analgesic pharmacologic classes. Although the main type of formulation available for buccal absorption is rapidly disintegrating tablets, new approaches include mucoadhesive tablets and spray formulations. Much of the current knowledge on the mechanism and characteristics of drug absorption from the buccal cavity has been gained from volunteer studies in which buffered drug solutions are placed in the mouth (buccal absorption model) rather than from clinical pharmacologic studies in patients. This former method provides useful information on the bioavailability of new and existing drugs. The main advantages of the buccal route of administration over the traditional peroral route are that drug degradation in the stomach is avoided, first-pass metabolism is avoided, and therapeutic blood levels of drug can be achieved rapidly. Clearly these advantages are presently clinically relevant for only a limited number of drugs. However, with the recent developments of formulation types, such as mucoadhesive preparations and the use of peptides as drugs, this number may increase in the future. The main disadvantage of the buccal route is that the drug may have an unwanted local effect in the mouth, such as bad taste, or may be absorbed slowly and, therefore, be swallowed prior to sufficient absorption taking place. The buccal route, like the rectal and intranasal routes, has been largely neglected by clinicians and manufacturing companies in the past and clearly merits further intensive research.

Senshang Lin

St. John's University, Jamaica, New York, U.S.A.

INTRODUCTION

Over the past decades, the treatment of illness has been accomplished by administering drugs to the human body via various pharmaceutical dosage forms, like tablets. These traditional pharmaceutical products are still commonly seen today in the prescription and over-the-counter drug marketplace. To achieve and maintain the drug concentration in the body within the therapeutic range required for a medication, it is often necessary to take this type of drug delivery system several times a day. This yields an undesirable “seesaw” drug level in the body (Fig. 1).

A number of advancements have been made recently in the development of new techniques for drug delivery. These techniques are capable of regulating the rate of drug delivery, sustaining the duration of therapeutic action, and/or targeting the delivery of drug to a specific tissue (1–6). These advancements have already led to the development of several novel drug delivery systems that could provide one or more of the following benefits:

1. Controlled administration of a therapeutic dose at a desirable rate of delivery
2. Maintenance of drug concentration within an optimal therapeutic range for prolonged duration of treatment
3. Maximization of efficacy-dose relationship
4. Reduction of adverse side effects
5. Minimization of the needs for frequent dose intake
6. Enhancement of patient compliance

Based on the technical sophistication of the controlled-release drug delivery systems (CrDDSs) that have been marketed so far, or that are under active development, the CrDDSs can be classified (Fig. 2) as follows:

1. Rate-preprogrammed drug delivery systems
2. Activation-modulated drug delivery systems
3. Feedback-regulated drug delivery systems
4. Site-targeting drug delivery systems

In this article, the scientific concepts and technical principles behind the development of this new generation of drug-delivery systems are outlined and discussed.

RATE-PREPROGRAMMED DRUG DELIVERY SYSTEMS

In this group of CrDDSs, the release of drug molecules from the delivery systems has been preprogrammed at a specific rate profile. This is accomplished by system design, which controls the molecular diffusion of drug molecules in and/or across the barrier medium within or surrounding the delivery system. Fick's laws of diffusion are often followed. These CrDDSs can further be classified as follows:

1. Polymer membrane permeation-controlled drug delivery systems
2. Polymer matrix diffusion-controlled drug delivery systems
3. Polymer (membrane/matrix) hybrid-type drug delivery systems
4. Microreservoir partition-controlled drug delivery systems

Polymer Membrane Permeation-Controlled Drug Delivery Systems

In this type of CrDDS, a drug formulation is either totally or partially encapsulated in a drug reservoir compartment whose drug-releasing surface is covered by a rate-controlling polymeric membrane. The drug reservoir can be drug solid particles, a dispersion of drug solid particles, or a concentrated drug solution in a liquid- or solid-type dispersing medium. The polymeric membrane can be fabricated from a homogeneous or a heterogeneous nonporous polymeric material or a microporous or semipermeable membrane. The encapsulation of drug formulation inside the reservoir compartment can be accomplished by molding, capsulation,

Fig. 1 Drug concentration profiles in the systemic circulation as a result of taking a series of multiple doses of a conventional drug-delivery system (A_1, A_2, \dots) in comparison with the ideal drug concentration profile (B). (Adapted from Ref. 6.)

microencapsulation, or other techniques. Different shapes and sizes of drug delivery systems can be fabricated (Fig. 3).

The release of drug from this type of CrDDSs should be at a constant rate (Q/t), which is defined by the following general equation:

$$\frac{Q}{t} = \frac{K_{m/r} K_{a/m} D_d D_m}{K_{m/r} D_m h_d + K_{a/m} D_d h_m} C_R \quad (1)$$

where $K_{m/r}$ and $K_{a/m}$ are, respectively, the partition coefficients for the interfacial partitioning of drug molecules from the reservoir to the membrane and from the membrane to the aqueous diffusion layer; D_m and D_d are, respectively, the diffusion coefficients in the rate-controlling membrane with a thickness of h_m , and in the aqueous diffusion layer with a thickness of h_d . For microporous membrane, the porosity, and tortuosity of the pores in the membrane should be included in the estimation of D_m and h_m . C_R is the drug concentration in the reservoir compartment.

The release of drug molecules from this type of CrDDS is controlled at a preprogrammed rate by modulating the partition coefficient and the diffusivity of drug molecule and the rate-controlling membrane and the thickness of the membrane. Several CrDDSs of this type have been successfully marketed for therapeutical uses and some representatives are outlined later for illustration.

Progestasert® IUD

In this controlled-release intrauterine device, the drug reservoir exists as a dispersion of progesterone crystals in silicone (medical grade) fluid encapsulated in the vertical limb of a T-shaped device walled by a nonporous membrane of ethylene–vinyl acetate copolymer (Fig. 4). It is engineered to release continuously a daily dose of 65 μg progesterone inside the uterine cavity to achieve

contraception for one year (6). The same technology has been utilized in the development of the Mirena® system, a plastic T-shaped frame with a steroid reservoir containing 52 mg levonorgestrel, which is designed to release a daily dose of levonorgestrel at $\sim 20 \mu\text{g}/\text{day}$ for achieving effective contraception for five years (7–9).

Ocusert® system

In this controlled-release ocular insert, the drug reservoir is a thin disc of pilocarpine–alginate complex sandwiched between two transparent discs of microporous membrane fabricated from ethylene–vinyl acetate copolymer (Fig. 5). The microporous membranes permit the tear fluid to penetrate into the drug reservoir compartment to dissolve pilocarpine from the complex. Pilocarpine molecules are then released at a constant rate of 20 or 40 $\mu\text{g}/\text{h}$ for a 4- to 7-day management of glaucoma (1, 6, 10, 11).

Transderm-Nitro® system

In this controlled-release transdermal therapeutic system, the drug reservoir, which is a dispersion of nitroglycerin–lactose triturate in a silicone (medical grade) fluid, is encapsulated in an ellipsoid-shaped thin patch. The drug reservoir is sandwiched between a drug-impermeable metallic plastic laminate, as the backing membrane, and a constant surface of drug-permeable, rate-controlling membrane of ethylene–vinyl acetate copolymer (Fig. 6). This device is fabricated by an injection-molding process. A thin layer of silicone adhesive is further coated on the drug-permeable membrane in order that an intimate contact of the drug-releasing surface with the skin surface is achieved and maintained. It is engineered to have nitroglycerin delivered transdermally at a rate of 0.5 (mg/cm^2)/day for a daily relief of angina (2, 3).

The same technology has been utilized in the development of the following: 1) the Estraderm® system, which administers a controlled dose of estradiol transdermally over 3–4 days for the relief of postmenopausal syndrome and osteoporosis (12–14); 2) the Duragesic® system, which provides a transdermal-controlled administration of fentanyl, a potent narcotic analgesic, for 72-h relief of chronic pain (14); and 3) the Androderm® system, which provides a transdermal-controlled delivery of testosterone, through nonscrotal skin, for the 24-h replacement therapy of testosterone-deficient patients (14).

Norplant® Subdermal Implant

The controlled-release subdermal implant is fabricated from a nonporous silicone (medical-grade) tubing, by sealing both ends with silicone (medical-grade) adhesive to encapsulate either levonorgestrel crystals alone (generation I) or a solid dispersion of levonorgestrel in

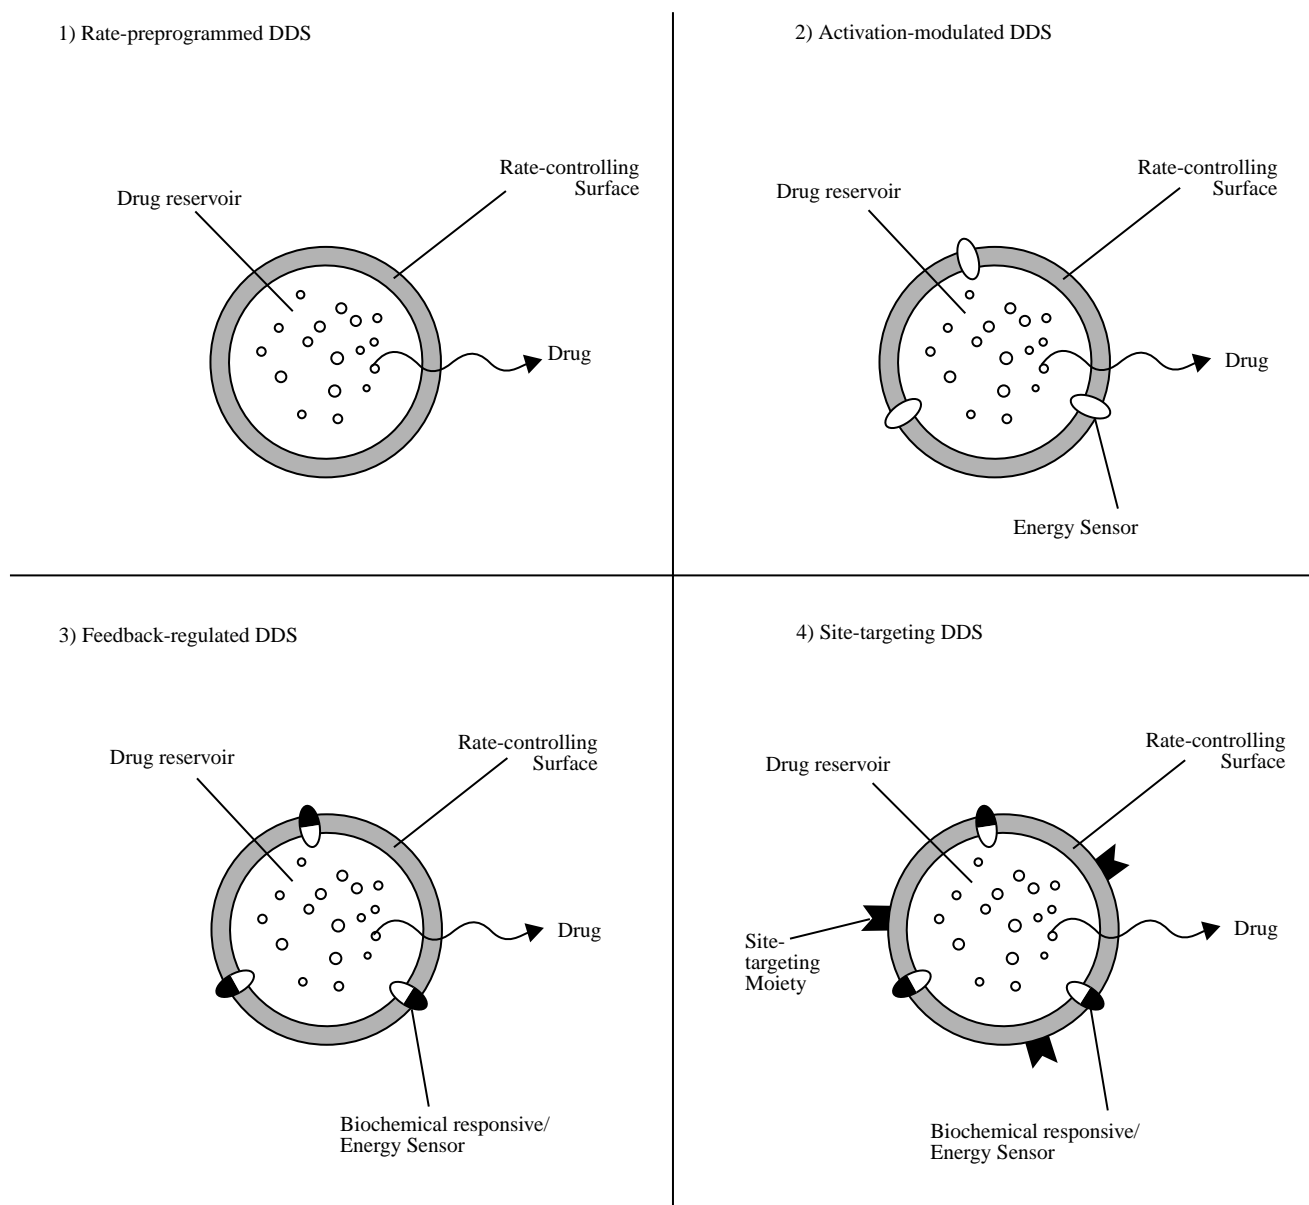

Fig. 2 The four major classes of controlled-release drug delivery systems.

silicone elastomer matrix (generation II). It is designed to attain a continuous release of levonorgestrel, at a daily dosage rate of 30 μg , to each subject (following the subcutaneous implantation of either 6 units of I or 2 units of II); (Fig. 7) for up to 7 years (15–18).

Polymer Matrix Diffusion-Controlled Drug Delivery Systems

In this type of CrDDS, the drug reservoir is produced from the homogeneous dispersion of drug particles in either a lipophilic or a hydrophilic polymer matrix.

The drug dispersion in the polymer matrix is accomplished by either 1) blending a dose of finely ground drug particles with a viscous liquid (or a semisolid) polymer, followed by a crosslinking of polymer chains or 2) mixing drug solids with a melted polymer at an elevated temperature. The resultant drug-polymer dispersion is then molded or extruded to form drug-delivery devices of various shapes and sizes designed for a specific application (Fig. 8). It can also be fabricated by dissolving the drug and the polymer in a common solvent, followed by solvent evaporation, at an elevated temperature and/or under a vacuum, in a mold.

Fig. 3 Release of drug from various shapes of polymer membrane permeation-controlled drug-delivery systems: (a) sphere-type, (b) cylinder-type, and (c) sheet-type. In (d), the drug concentration gradients across the rate-controlling polymeric membrane and hydrodynamic diffusion layer exist in series. Both the polymer membrane, which is either porous or nonporous, and the diffusion layer have a controlled thickness (h_m and h_d , respectively).

Fig. 6 Cross-sectional view of a unit of Transderm-Nitro® system, showing various structural components, and plasma concentration profiles of nitroglycerin in 14 human volunteers, each receiving one unit of Transderm-Nitro system (20 cm², with a delivery rate of 10 mg/day) for 24 h. (From Refs. 11, 55.)

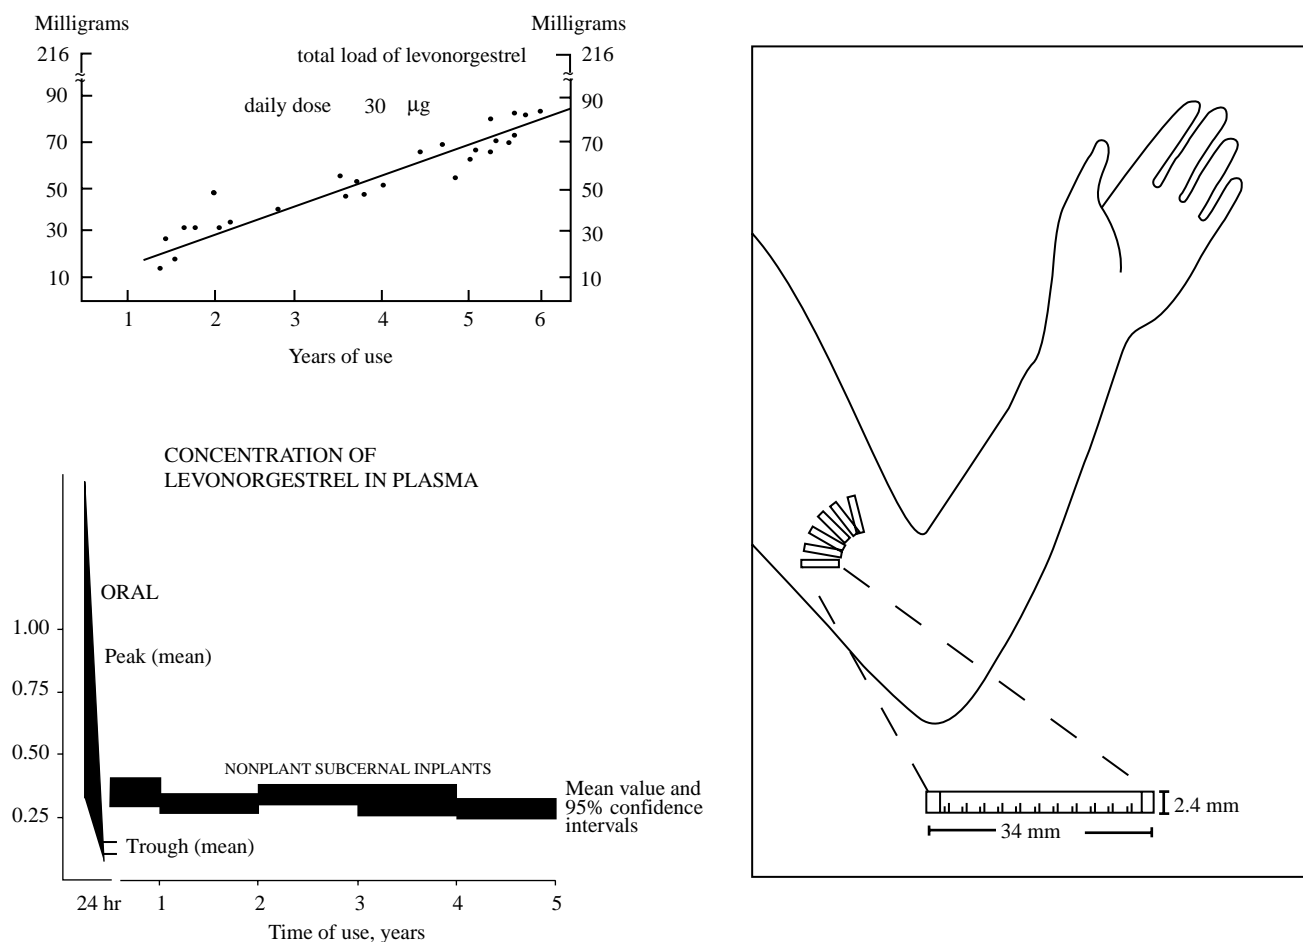

Fig. 7 Diagrammatic illustration of the subcutaneous implantation of Norplant® implants. The subcutaneous release profile of levonorgestrel in female volunteers for up to 6 years and the resultant plasma profile as compared to those obtained by oral administration. (Adapted from Refs. 15–18.)

The release profile of drug from this matrix diffusion-controlled CrDDS is not constant, because the rate of drug release is time dependent as defined by:

$$\frac{Q}{t^{1/2}} = (2AC_R D_p)^{1/2} \quad (2)$$

where A is the initial loading dose of drug dispersed in the polymer matrix; C_R is the drug solubility in the polymer, which is also the drug reservoir concentration in the polymer matrix; and D_p is the diffusivity of the drug molecules in the polymer matrix.

The release of drug molecules from this type of CrDDSs may be controlled at a preprogrammed rate by controlling the loading level and the polymer solubility of the drug and its diffusivity in the polymer matrix. Several CrDDSs of this type have been successfully marketed for therapeutical uses, and some representatives are outlined later for illustration.

Nitro-Dur® System

This controlled-release transdermal therapeutic system is fabricated by first heating an aqueous solution of water-soluble polymer, glycerol, and polyvinyl alcohol and then lowering the temperature of the mixture to form a polymer gel. Nitroglycerin/lactose triturate is dispersed in the gel, and the mixture is then solidified at room temperature to form a medicated polymer disc by a molding and slicing technique. After assembly onto a drug-impermeable metallic plastic laminate, a patch-type transdermal therapeutic system is produced with an adhesive rim surrounding the medicated disc (Fig. 9). It is designed for application onto an intact skin to provide a continuous transdermal infusion of nitroglycerin, at a daily dose of 0.5 mg/cm^2 , for the prevention of angina pectoris (2, 19).

The drug reservoir can also be formulated by directly dispersing the drug in an adhesive polymer, such as poly(isobutylene) or poly(acrylate) adhesive, and then

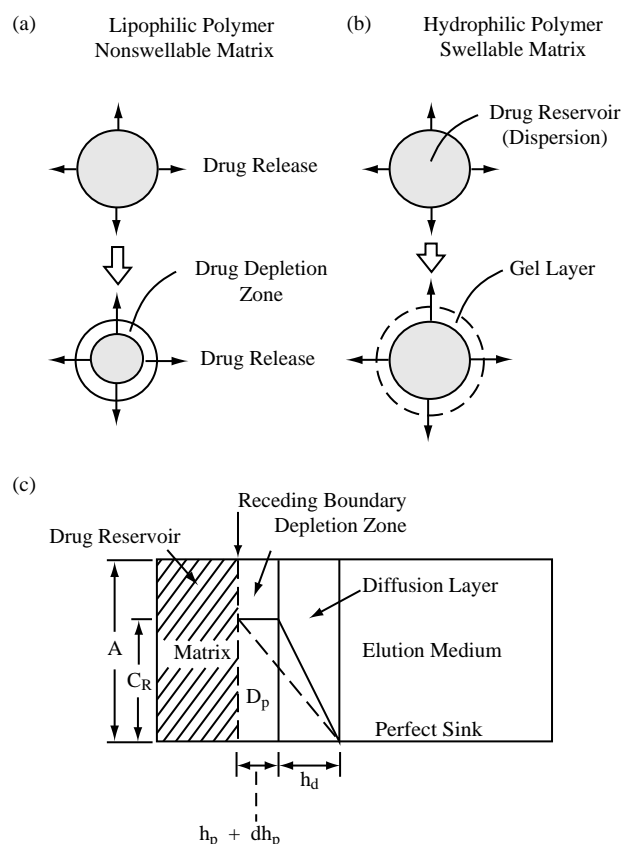

Fig. 8 Release of drug from the polymer matrix diffusion-controlled drug delivery systems with drug reservoir exists as a homogeneous dispersion in (a) lipophilic, nonswellable polymer matrix, with a growing thickness of drug depletion zone, or (b) a hydrophilic, swellable polymer matrix, with a growing thickness of drug-depleted gel layer. In (c), the drug concentration gradients across the time-dependent drug depletion zone, with a growing thickness ($h_p + dh_p$), and the hydrodynamic diffusion layer, with a controlled thickness (h_d), are shown in series.

spreading the medicated adhesive by solvent casting or hot melt, onto a flat sheet of drug-impermeable backing support to form a single- or multiple-layer drug reservoir. This type of transdermal CrDDS (TDD) is best illustrated by the development and marketing of an isosorbide dinitrate-releasing TDD system, named Frandol[®] tape, by Toaeiyo/Yamanouchi in Japan, and of a nitroglycerin-releasing TDD system, named Nitro-Dur[®] II system by Key in the United States, for once-a-day medication for angina pectoris. This second generation of TDD system (NitroDur II) has also received FDA approval for marketing. Nitro-Dur II compares favorably with Nitro-Dur (Fig. 10) and has gradually replaced the first-generation Nitro-Dur from the marketplace. The same technical basis has been also utilized in the development of the following: 1) Habitrol[®] and Nicotrol[®] systems, which

provide a controlled dose of nicotine transdermally over 24 h for smoking cessation (14); 2) Minitran[®] system, which administers a controlled dose of nitroglycerin transdermally over 24 h for the relief of anginal attacks (14); 3) Testoderm[®] system, which administers a controlled delivery of testosterone for transdermal permeation through a scrotal skin (14) for the replacement therapy of testosterone-deficient patients for 24 h; and 4) Climara[®] system, which provides a controlled delivery of 17 β -estradiol for transdermal permeation for once-weekly treatment of vasomotor systems (14) associated with menopause.

Compodose[®] Implant

This controlled-release subdermal implant is fabricated by dispersing micronized estradiol crystals in a viscous mixture of silicone elastomer and catalyst and then coating the estradiol-polymer dispersion around a rigid (drug-free) silicone rod by an extrusion technique to form a cylinder-shaped implant (Fig. 11). This implant is designed for subcutaneous implantation in the steer's ear flap for a duration of 200 or 400 days, during which a controlled quantity of estradiol is released daily for growth promotion (20).

To improve the Q versus $t^{1/2}$ drug release profiles [Eq. (2)], this polymer matrix diffusion-controlled CrDDS can be modified to have the drug-loading level varied, in an incremental manner, to form a gradient of drug reservoir along the diffusional path in the polymer matrix. A constant drug release profile is thus achieved, and the rate of drug release from this drug reservoir gradient-controlled drug delivery system is defined by:

$$\frac{dQ}{dt} = \frac{K_{a/r} D_a}{h_a(t)} C_p(h_a) \quad (3)$$

in which the time-dependent thickness [$h_a(t)$] of the diffusional path for drug molecules to diffuse through, which is increasing with time, is compensated by the proportional increase in the drug-loading level [$C_p(h_a)$], and a constant drug release profile is thus obtained. This type of CrDDS is best illustrated by the nitroglycerin-releasing Deponit[®] system (Fig. 12), first marketed by Pharma-Schwartz/Lohmann in Europe (21). Wyeth-Ayerst has received FDA approval for marketing this system in the United States.

Furthermore, it was recently demonstrated that the release of a drug, such as propranolol, from the multilaminate adhesive-based TDD system can be maintained at zero-order kinetics by controlling the particle size distribution of drug crystals in the various laminates of adhesive matrix (22).

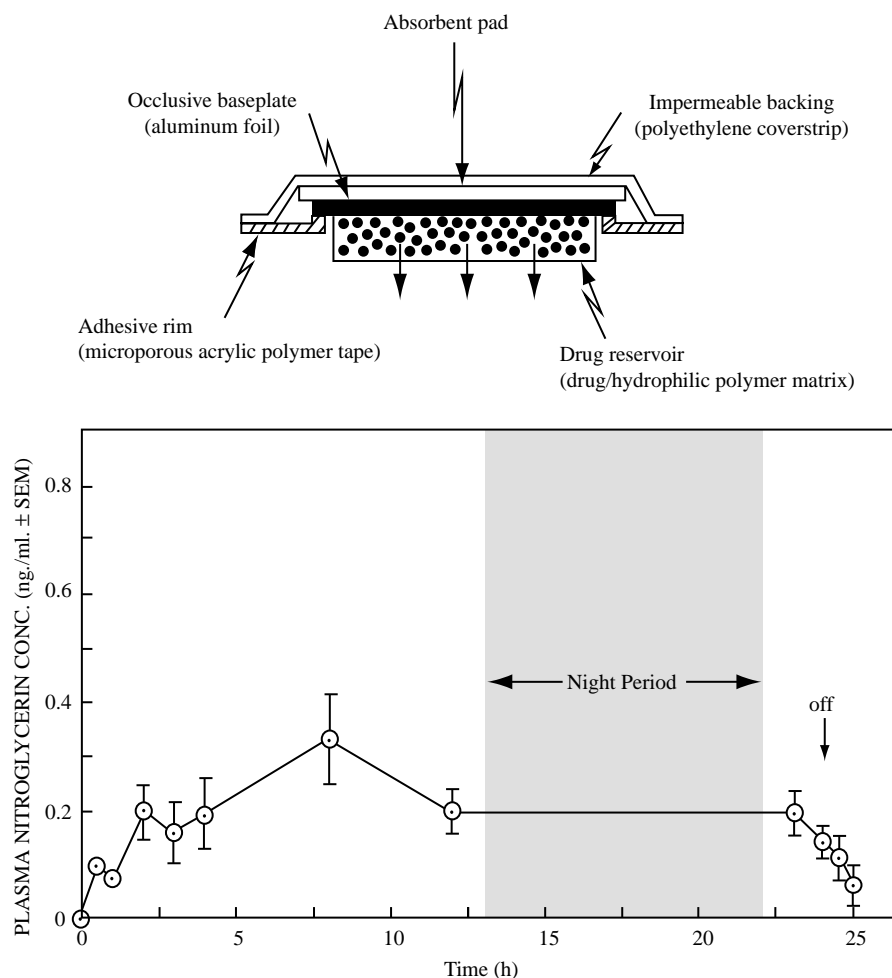

Fig. 9 Cross-sectional view of a unit of Nitro-Dur[®] system, showing various structural components, and the plasma nitroglycerin concentration profiles in six human volunteers, each receiving 1 unit of Nitro-Dur[®] system (20 cm², with a delivery rate of 10 mg/day) for 24 h. (From Refs. 55 and 56.)

Polymer (Membrane/Matrix) Hybrid-Type Drug Delivery Systems

This type of CrDDS is developed with the objective of combining the constant drug release kinetics of polymer membrane permeation-controlled drug delivery systems with the mechanical superiority of polymer matrix diffusion-controlled drug delivery systems. The release profile of drug from a sandwich-type drug delivery system (Fig. 13) is constant, and the instantaneous rate of drug release is defined by:

$$\frac{dQ}{dt} = \frac{AC_p D_p}{[D_p K_m (1/P_m + 1/P_d)]^2 + 4AC_p D_p t^{1/2}} \quad (4)$$

where A is the initial amount of drug solid impregnated in a unit volume of polymer matrix with solubility C_p and

diffusivity D_p ; K_m is the partition coefficient for the interfacial partitioning of drug molecules from polymer matrix toward polymer coating membrane; P_m is the permeability coefficient of the polymer coating membrane with thickness h_m ; and P_d is the permeability coefficient of the hydrodynamic diffusion layer with thickness h_d .

The hybrid system is exemplified by the development of clonidine-releasing and scopolamine-releasing transdermal therapeutic systems (Catapres-TTS[®] and Transderm-Scop[®]) (Fig. 14), in which a rate-controlling nonmedicated polymeric membrane is added to coat the surface of the drug-dispersing polymer matrix, and the release of drug molecules thus becomes controlled by membrane permeation instead of matrix diffusion. The same technology has been utilized in the development of levonorgestrel-releasing subdermal implants (Norplant[®] II).

Fig. 10 Cross-sectional view of Nitro-Dur II, showing various structural components, and the comparative 24-h plasma nitroglycerin concentration profiles in 24 healthy male volunteers, each receiving randomly 1 unit of Nitro-Dur II (open circle) or Nitro-Dur (closed circle), 20 cm² each, with a delivery rate of 10 mg/day, over the chest for 24 h (the arrow indicates unit removal). (From Ref. 56.)

Microreservoir Partition-Controlled Drug Delivery Systems

In this type of CrDDS, the drug reservoir is a suspension of drug solid particles in an aqueous solution of a water-miscible polymer, like polyethylene glycols. This forms a homogeneous dispersion of many discrete, unleachable, microscopic drug reservoirs in a biocompatible polymer, like silicone elastomers (Fig. 15). The microdispersion is achieved by applying a high-energy dispersion technique (13, 23). Different shapes and sizes of drug-delivery devices can be fabricated from this microreservoir-type CrDDS by molding or extrusion techniques. Depending upon the physicochemical properties of drugs and the desired rate of drug release, the device can be further coated with a layer of biocompatible polymer to modify the mechanism and the rate of drug release.

The rate of drug release (dQ/dt) from this type of CrDDS is defined by:

$$\frac{dQ}{dt} = \frac{D_p D_a m K_p}{D_p h_d + D_a h_p m K_p} \left[n S_p - \frac{D_l S_l (1-n)}{h_l} \left(\frac{1}{K_l} + \frac{1}{K_m} \right) \right] \quad (5)$$

where $m = a/b$ and n is the ratio of drug concentration at the inner edge of the interfacial barrier over the drug

Fig. 11 Diagrammatic illustration of a unit of Compudose® subdermal implant and in vitro release profiles of estradiol from the implants immersed in aqueous solution containing various volume fractions of polyethylene glycol 400.

solubility in the polymer matrix (1, 6), in which a is the ratio of drug concentration in the bulk of elution solution over drug solubility in the same medium and b is the ratio of drug concentration at the outer edge of the polymer coating membrane over drug solubility in the same polymer. K_l , K_m , and K_p are, respectively, the partition coefficients for the interfacial partitioning of drug from the liquid compartments to the polymer matrix, from the polymer matrix to the polymer coating membrane, and from the polymer coating membrane to the elution solution, whereas D_l , D_p , and D_d are, respectively, the diffusivities of the drug in the liquid layer surrounding the drug particles, the polymer coating membrane enveloping the polymer matrix, and the hydrodynamic diffusion layer surrounding the polymer coating

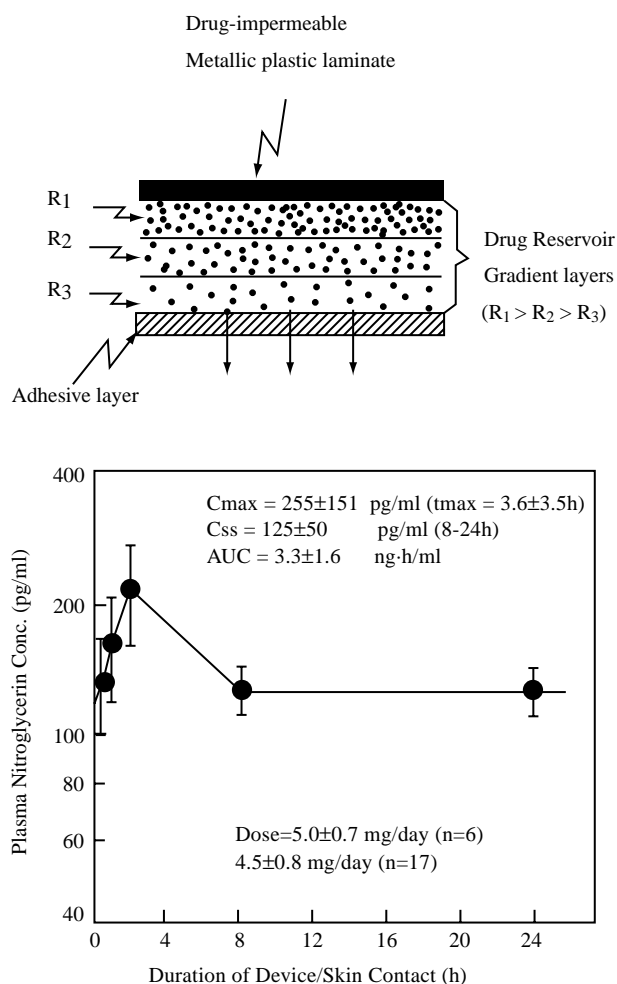

Fig. 12 Cross-sectional view of a unit of Deponit® system, showing various structural components, and the plasma nitroglycerin concentration profiles in six human volunteers, each receiving 1 unit of Deponit system (16 cm², with a delivery rate of 5 mg/day) for 24 h. (Plasma profiles are plotted from data from Ref. 21.)

membrane with respective thicknesses of h_i , h_p , and h_d (Fig.15); and S_l and S_p are the solubilities of the drug in the liquid compartments and in the polymer matrix, respectively.

The release of drug from the microreservoir-type CrDDS can follow either a dissolution- or a matrix diffusion-control process, depending upon the relative magnitude of S_l and S_p (24). Representatives of this type of CrDDS is outlined below.

Nitrodisc® system

In this transdermal CrDDS (Fig. 16), the drug reservoir is a suspension of nitroglycerin/lactose triturate in an

aqueous solution of 40% polyethylene glycol 400. It is dispersed homogeneously by a high-energy mixing technique, with isopropyl palmitate, a skin permeation enhancer, in a mixture of viscous silicone elastomer and catalyst (25). The resultant drug-polymer dispersion is then formed in situ into a solid medicated disc on a drug-impermeable metallic plastic laminate, with an adhesive rim, by an injection-molding technique and application of an instantaneous heating. It is engineered to provide a transdermal administration of nitroglycerin at a daily rate of 0.5 mg/cm² for once-a-day medication of angina pectoris (2, 26). AQ versus $t^{1/2}$ (matrix diffusion-controlled) release profile is obtained.

Syncro-Mate-C implant

This subdermal controlled-release implant is fabricated by dispersing the drug reservoir, which is a suspension of norgestomet in an aqueous solution of PEG 400, in a viscous mixture of silicone elastomers by a high-energy dispersion technique (24). After adding catalyst, the suspension is delivered into a silicone medical-grade tubing, which serves as the mold as well as the coating membrane, and then polymerized in situ. The polymerized drug-polymer composition is then cut into a cylinder-shaped implant with its ends staying open (Fig. 17). This tiny cylindrical implant is designed to be inserted into the subcutaneous tissue of the livestock's ear flap; norgestomet is released continuously into the subcutaneous tissue for up to 20 days for the control and synchronization of estrus and ovulation and up to 160 days for growth promotion. A constant Q versus t (dissolution-controlled) release profile has been achieved, as compared to the Q versus $t^{1/2}$ release profile (matrix diffusion-controlled drug release) for the Syncro-Mate-B implant and the Nitrodisc system discussed above.

Transdermal contraceptive device

The transdermal contraceptive device is based on a patentable micro-drug-reservoir technique (26) to achieve a dual-controlled release of levonorgestrel, a potent synthetic progestin, and estradiol, a natural estrogen, at constant and enhanced rates, continuously, for a period of 7 days (5). By applying 1 unit (10 or 20 cm²) of transdermal contraceptive device per week, beginning on day 5 of an individual's menstrual cycle, for 3 consecutive weeks (3 weeks on and 1 week off), steady-state serum levels of levonorgestrel have been obtained, and the secretion of gonadotropins and progesterone have been effectively suppressed.

Fig. 13 The controlled release of drug molecules from a (membrane-matrix) hybrid-type drug delivery system in which solid drug is homogeneously dispersed in a polymer matrix, which is then encapsulated inside a polymeric membrane, where D , P , and h are the diffusivity, permeability, and thickness, respectively, and the subscripts p, m, and d denote the drug depletion zone in the polymer matrix, polymer coating membrane, and diffusion layer, respectively.

Fig. 16 Cross-sectional view of a unit of Nitrodisc® system, showing various structural components, and the plasma nitroglycerin concentration profiles in 12 human volunteers, each receiving 1 unit of Nitrodisc system (16 cm², with a delivery rate of 10 mg/day) for 32 h. (From Ref. 23.)

ACTIVATION-MODULATED DRUG DELIVERY SYSTEMS

In this group of CrDDSs, the release of drug molecules from the delivery systems is activated by some physical, chemical, or biochemical processes and/or facilitated by an energy supplied externally (Fig. 2). The rate of drug release is then controlled by regulating the process applied or energy input. Based on the nature of the process applied or the type of energy used, these activation-modulated CrDDSs can be classified into the following categories:

1. Physical means
 - a. Osmotic pressure-activated drug delivery systems
 - b. Hydrodynamic pressure-activated drug delivery systems
 - c. Vapor pressure-activated drug delivery systems
 - d. Mechanical force-activated drug delivery systems
 - e. Magnetics-activated drug delivery systems
 - f. Sonophoresis-activated drug delivery systems
 - g. Iontophoresis-activated drug delivery systems
 - h. Hydration-activated drug delivery systems
2. Chemical means
 - a. pH-activated drug delivery systems
 - b. pH-activated drug delivery systems

Fig. 17 Syncro-Mate-C implant, a subdermal implant fabricated from the microreservoir dissolution-controlled drug-delivery system, and subcutaneous controlled release of norgestomet, a potent synthetic progestin, at constant rate for 20 days. The open ends on the implant do not affect the zero-order in vivo drug release profile. (Adapted from Ref. 57.)

- c. Ion-activated drug delivery systems
- d. Hydrolysis-activated drug delivery systems

3. Biochemical means

- a. Enzyme-activated drug delivery systems
- b. Biochemical-activated drug delivery systems

Several CrDDSs have been successfully developed and applied clinically to the controlled delivery of pharmaceuticals and biopharmaceuticals. These are outlined and discussed below.

Osmotic Pressure-Activated Drug Delivery Systems

In this type of CrDDSs, the drug reservoir, which can be either a solution or a solid formulation, is contained within a semipermeable housing with a controlled water permeability. The drug in solution is released through a special laser-drilled delivery orifice at a constant rate under a controlled gradient of osmotic pressure.

For a solution-type osmotic pressure-activated CrDDS, the intrinsic rate of drug delivery (Q/t) is defined by:

$$\frac{Q}{t} = \frac{P_w A_m}{h_m} (\pi_s - \pi_e) \quad (6)$$

For a solid-type osmotic pressure-activated CrDDS, the intrinsic rate of drug delivery should also be a constant and is defined by:

$$\frac{Q}{t} = \frac{P_w A_m}{h_m} (\pi_s - \pi_e) S_d \quad (7)$$

where P_w , A_m , and h_m are, respectively, the water permeability, the effective surface area, and the thickness of the semipermeable housing; $(\pi_s - \pi_e)$ is the differential

osmotic pressure between the drug-delivery system with an osmotic pressure of π_s and the environment with an osmotic pressure of π_e ; and S_d is the aqueous solubility of the drug component in the solid reservoir.

The release of drug molecules from this type of CrDDS is activated by osmotic pressure and controlled at a rate determined by the water permeability and the effective surface area of the semipermeable housing as well as the osmotic pressure gradient. Several CrDDSs of this type have been successfully marketed for therapeutical uses and some representatives are outlined later.

Alzet osmotic pump

In this implantable or insertable CrDDS, the drug reservoir, which is normally a solution formulation, is contained within a collapsible, impermeable polyester bag whose external surface is coated with a layer of osmotically active salt, for example, sodium chloride. This reservoir compartment is then totally sealed inside a rigid housing walled with a semipermeable membrane (Fig. 19). At an implantation site, the water content in the tissue fluid will penetrate through the semipermeable membrane at a controlled rate and dissolve the osmotically active salt. This creates an osmotic pressure in the narrow spacing between the flexible reservoir wall and the rigid semipermeable housing. Under the osmotic pressure created [Eq. (6)], the reservoir compartment is thus reduced in volume and the drug solution is forced to release through the flow moderator at a controlled rate (27, 28). By varying the drug concentration in the solution, different doses of drug can be delivered at a constant rate for a period of 1–4 weeks.

In addition to its application in the subcutaneous controlled administration of drugs for pharmacological studies, this technology has recently been extended to the controlled administration of drugs in the rectum by zero-order kinetics. The hepatic first-pass metabolism of drugs is thus bypassed (29).

Acutrim[®] tablet

In this oral CrDDS, the drug reservoir, which is a solid tablet of water-soluble and osmotically-active phenylpropanolamine (PPA) HCl, is enclosed within a semipermeable membrane of cellulose triacetate (2, 30). The surface of the semipermeable membrane is further coated with a thin layer of immediately releasable PPA dose (Fig. 20). In the alimentary tract, the gastrointestinal fluid will dissolve away the immediate release layer of PPA to provide an initial dose of PPA and then penetrate through the semipermeable membrane to dissolve the sustained-release dose of PPA. Under the osmotic pressure created [Eq. (7)], the PPA solution is released continuously at a

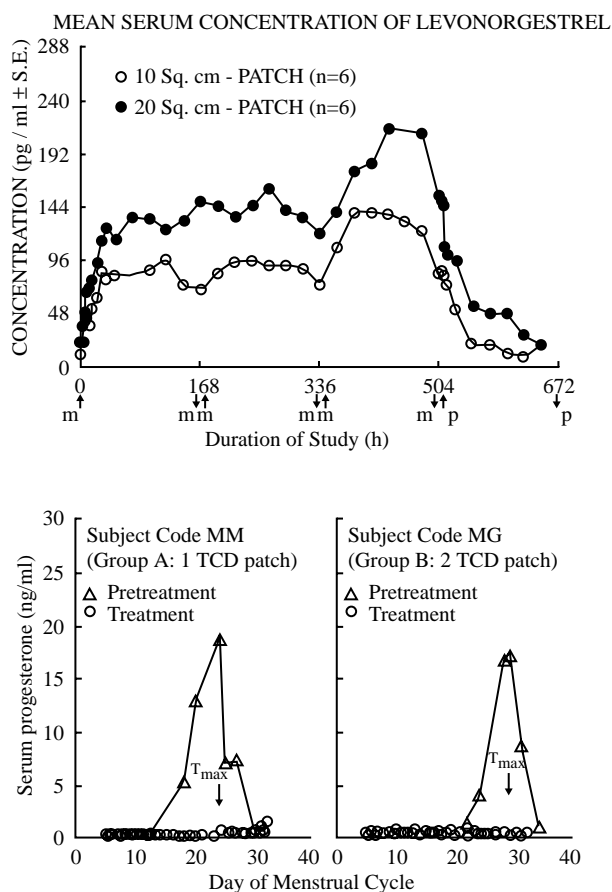

Fig. 18 (Upper panel) The 4-week serum levonorgestrel profiles in 12 human volunteers, each receiving 1 or 2 units of a transdermal contraceptive system (10 cm², with daily dosage of 28.3 μg/day) once a week, consecutively for 3 weeks, and the same size of placebo on week 4. (Lower panel) Comparative serum concentration profiles of progesterone during the pretreatment and treatment cycles in two subjects, each as the representative for group A (receiving 10 cm²) and group B (receiving 20 cm²), respectively. The suppression of progesterone peak during the treatment cycle is an indication of effective fertility control.

(Right panel) The effect of 7 days of subcutaneous delivery of antidiuretic hormone (vasopressin) on the daily volume of urinary excretion and urine osmolality in the Brattleboro rats with diabetes insipidus.

controlled rate, through an orifice pre-drilled by a laser beam (2, 30, 31). It is designed to provide a controlled delivery of PPA over a duration of 16 h for appetite suppression in a weight-control program (31). The same delivery system has also been utilized for the oral controlled delivery of indomethacin. An extension of this technology is the development of a push-pull type osmotic pressure-activated CrDDS for the oral controlled delivery of nifedipine and metoprolol (27). It has been further extended to the delayed-onset and controlled oral delivery of verapamil (14) to produce a maximum plasma concentration in the morning hours.

Hydrodynamic Pressure-Activated Drug Delivery Systems

In addition to the osmotic pressure systems discussed above, hydrodynamic pressure has also been explored as the potential source of energy to modulate the delivery of therapeutic agents (2).

A hydrodynamic pressure-activated drug-delivery system can be fabricated by placing a liquid drug formulation inside a collapsible, impermeable container to form a drug reservoir compartment. This is then contained inside a rigid, shape-retaining housing. A laminate of an absorbent layer and a swellable, hydrophilic polymer layer is sandwiched between the drug reservoir compartment and the housing. In the gastrointestinal tract, the laminate will imbibe the gastrointestinal fluid through the annular openings at the lower end of the housing and become swollen. This generates a hydrodynamic pressure in the system. The hydrodynamic pressure, thus created, forces the drug reservoir compartment to reduce in volume and causes the liquid drug formulation to release through the delivery orifice (32). The drug release rate is defined by

$$\frac{Q}{t} = \frac{P_f A_m}{h_m} (\theta_s - \theta_e) \quad (8)$$

Fig. 20 Cross-sectional view of a unit of Acutrim[®] tablet, a solid-type osmotic pressure-activated drug delivery system, and the effect of increased osmotic pressure in the dissolution medium on the release profiles of phenylpropanolamine HCl from the Acutrim tablet at intestinal condition. (Adapted from Refs. 31 and 58.)

where P_f , A_m , and h_m are the fluid permeability, the effective surface area, and the thickness of the wall with annular openings, respectively; and $\theta_s - \theta_e$ is the difference in hydrodynamic pressure between the drug delivery system (θ_s) and the environment (θ_e).

The release of drug molecules from this type of CrDDS is activated by hydrodynamic pressure and controlled at a rate determined by the fluid permeability and effective surface area of the wall with annular openings as well as by the hydrodynamic pressure gradient.

Vapor Pressure-Activated Drug Delivery Systems

In this type of CrDDS, the drug reservoir, which is a solution formulation, is contained inside the infusion compartment. It is physically separated from the pumping compartment by a freely movable partition (Fig. 21). The pumping compartment contains a vaporizable fluid, such as fluorocarbon, which vaporizes at body temperature and creates a vapor pressure. Under the vapor pressure created, the partition moves upward and forces the drug solution in the infusion compartment to be delivered, through a series of flow regulator and delivery cannula, into the blood circulation at a constant flow rate (1, 6, 33). The process is defined by:

$$\frac{Q}{t} = \frac{d^4 \delta P}{40.74 \mu l} \quad (9)$$

where d and l are, respectively, the inner diameter and the length of the delivery cannula; Δp is the pressure difference between the vapor pressure in the pumping compartment and the pressure at the implantation site; and μ is the viscosity of the drug formulation.

The delivery of drug from this type of CrDDS is activated by vapor pressure and controlled at a rate determined by the differential vapor pressure, the formulation viscosity, and the size of the delivery cannula.

A typical example is the development of Infusaid[®], an implantable infusion pump by Metal Bellows, for the constant infusion of heparin in anticoagulation treatment (34), of insulin in the normoglycemic control of diabetics (33), and of morphine for patients suffering from the intensive pain of a terminal cancer (35).

Mechanical Force-Activated Drug Delivery Systems

In this type of CrDDS, the drug reservoir is a solution formulation in a container equipped with a mechanically activated pumping system. A metered dose of drug formulation can be reproducibly delivered into a body cavity, such as the nose, through the spray head upon manual activation of the drug-delivery pumping system. The volume of solution delivered is fixed and is independent of the force and duration of activation.

A typical example of this type of drug-delivery system is the development of a metered-dose nebulizer for the intranasal administration of a precision dose of luteinizing hormone-releasing hormone (LHRH) and its synthetic analogs, such as buserelin. Through nasal absorption, the hepatic first-pass elimination of these peptide drugs is thus avoided (24).

Magnetic-Activated Drug Delivery Systems

Macromolecular drugs, such as peptides, have been known to release only at a relatively low rate from a polymer-controlled drug-delivery system. This low rate of release can be improved by incorporating an electromagnetism-triggering vibration mechanism into the polymeric delivery device. With a hemispheric-shaped design, a zero-order drug-release profile is achieved (36). By combining these two approaches, a subdermally implantable, magnetic-activated hemispheric drug-delivery device is developed. It is fabricated by first positioning a tiny doughnut-shaped magnet at the center of a drug-dispersing biocompatible polymer matrix and

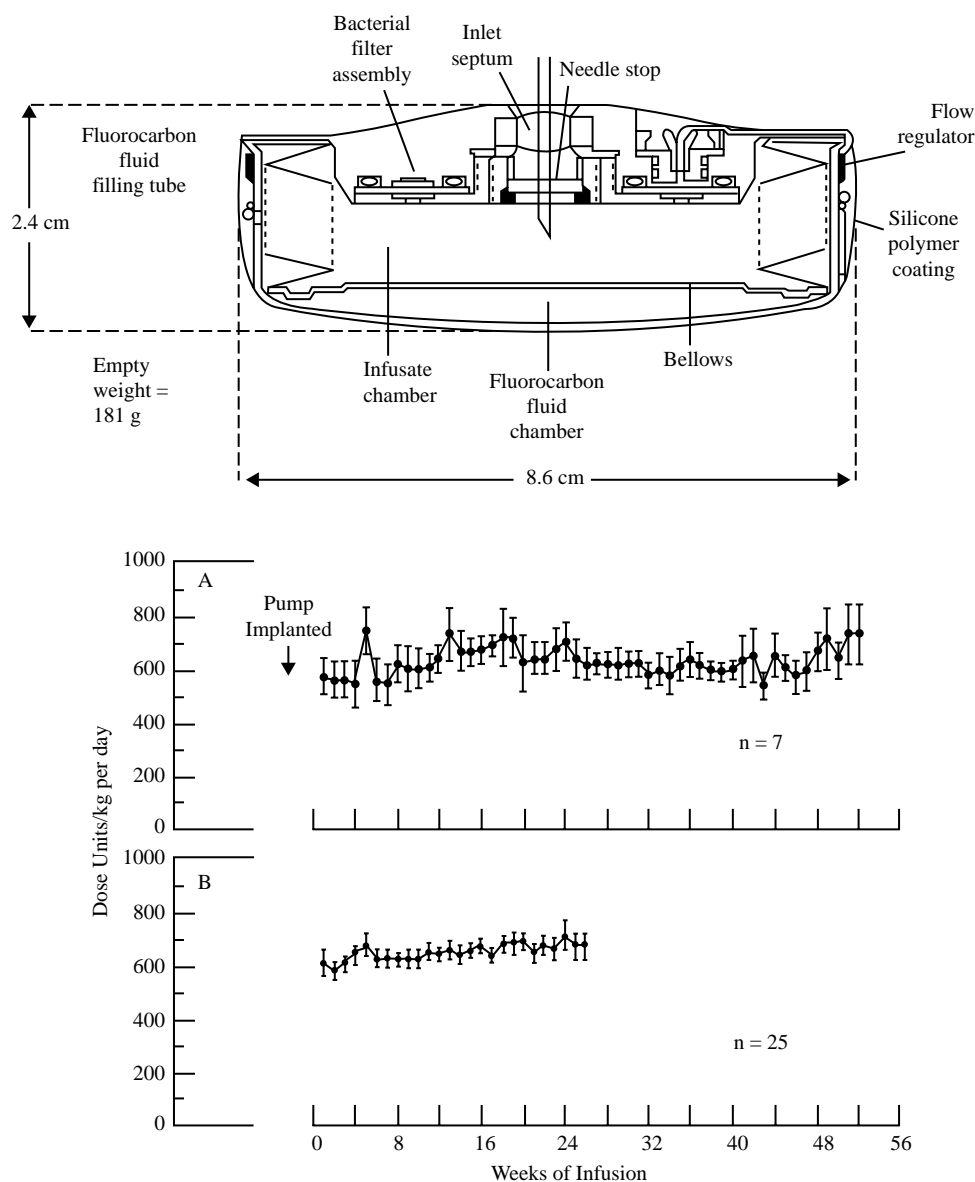

Fig. 21 Cross-sectional view of a unit of Infusaid® system, a vapor pressure-activated drug-delivery system, and daily heparin dose (mean \pm S.E.) delivered to 25 dogs for 6 months and to 7 dogs for 12 months. (Adapted from Ref. 34.)

then coating the external surface of the medicated polymer matrix, with the exception of one cavity at the center of the flat surface, with a pure polymer, for instance, ethylene–vinyl acetate copolymer or silicone elastomers. This uncoated cavity is designed for allowing a peptide drug to release.

The hemispheric magnetic delivery device produced can release macromolecular drugs, like bovine serum albumin, at a low basal rate, by diffusion process, and under a nontriggering condition, or it can release the same

drug at a much higher rate, when the magnet is activated, to vibrate by an external electromagnetic field.

Sonophoresis-Activated Drug Delivery Systems

This type of activation-controlled drug delivery system utilizes ultrasonic energy to activate (or trigger) the delivery of drugs from a polymeric drug delivery device. The system can be fabricated from either a nondegradable polymer, such as ethylene–vinyl acetate copolymer, or a

bioerodible polymer, such as poly[bis(*p*-carboxyphenoxy)alkane anhydride] (37). The potential application of sonophoresis (or phonophoresis) to regulate the delivery of drugs was recently reviewed (38).

Iontophoresis-Activated Drug Delivery Systems

This type of CrDDS use electrical current to activate and to modulate the diffusion of a charged drug molecule across a biological membrane, such as the skin, in a manner similar to passive diffusion under a concentration gradient but at a much facilitated rate. The iontophoresis-facilitated skin permeation rate of a charged molecule *i* consists of three components and is expressed by

$$J_i^{\text{isp}} = J^p + J^e + J^c = \left(K_s D_s \frac{dC}{h_s} \right) + \left(\frac{Z_i D_i F_i}{RT} C_i \frac{dE}{h_s} \right) + (k C_s I_d) \quad (10)$$

where J^p , J^e , and J^c represent, respectively, the flux for the skin permeation by passive diffusion, for the electrical current-driven permeation, and for the convective flow-driven skin permeation; K_s is the partition coefficient for interfacial partitioning from the donor solution to the stratum comeum; D_s and D_i are, respectively, the diffusivity across the skin and the diffusivity of ionic species *i* in the skin; C_i and C_s are, respectively, the donor concentration of ionic species *i* and the concentration in the skin tissue; dE/h_s is the electrical potential gradient across the skin; dC/h_s is the concentration gradient across the skin; Z_i is the electrical valence of ionic species *i*; I_d is the current density applied; F , k , and R are, respectively, the faraday, proportionality, and gas constant; and T is the absolute temperature.

A typical example of this type of activation-controlled CrDDS is the development of an iontophoretic drug delivery system, named Phoresor by Motion Control, to facilitate the percutaneous penetration of antiinflammatory drugs, such as dexamethasone sodium phosphate (39–41), to surface tissues.

Further development of the iontophoresis-activated drug delivery technique has yielded a new design of iontophoretic drug delivery system—the transdermal periodic iontotherapeutic system (TPIS). This new system, which is capable of delivering a physiologically-acceptable pulsed direct current, in a periodic manner, with a special combination of waveform, intensity, frequency, and on/off ratio, for a specific duration, has significantly improved the efficiency of transdermal delivery of peptide and protein drugs (4). A typical example is the iontophoretic transdermal delivery of insulin, a protein drug, in the control of hyperglycemia in diabetic animals.

Hydration-Activated Drug Delivery Systems

In this type of CrDDS, the drug reservoir is homogeneously dispersed in a swellable polymer matrix fabricated from a hydrophilic polymer. The release of drug is activated and modulated by hydration-induced swelling of the polymer matrix. Representatives of this type of CrDDS are outlined below.

Syncro-Male-B implant

This subcutaneous CrDDS is fabricated by dissolving norgestomet, a potent progestin for estrus synchronization, in an alcoholic solution of linear ethylene glycomethacrylate polymer (Hydron S). The drug-polymer mixture is then cross-linked by adding ethylene dimethacrylate, in the presence of an oxidizing catalyst, to form a cylinder-shaped subdermally implantable implant (1, 6). This tiny subdermal implant can be activated by tissue fluid to swell and can be engineered to deliver norgestomet, at a rate of $504 \mu\text{g}/\text{cm}^2/\text{day}^{1/2}$, in the subcutaneous tissue for up to 16 days for the control and synchronization of estrus in livestock (13).

Valrelease[®] tablet

This oral CrDDS is prepared by granulating Valium, an antidepressant drug, with hydrocolloids (20–75 wt%) and pharmaceutical excipients. The granules are then compressed to form an oral tablet. After oral intake, the hydrocolloids absorb the gastric fluid and are activated to form a colloid gel matrix surrounding the tablet surface (Fig. 22). The release of Valium molecules is then controlled by diffusion through the gel barrier, while the tablet remains buoyant in the stomach, due to a density difference between the gastric fluid ($d > 1$) and the gelling tablet ($d < 1$) (2, 3).

pH-Activated Drug Delivery Systems

For a drug labile to gastric fluid or irritating to gastric mucosa, this type of CrDDS has been developed to target the delivery of the drug only in the intestinal tract, not in the stomach (2). It is fabricated by coating a core tablet of the gastric fluid-sensitive drug with a combination of intestinal fluid-insoluble polymer, like ethyl cellulose, and intestinal fluid-soluble polymer, like hydroxymethyl cellulose phthalate (Fig. 23).

In the stomach, the coating membrane resists the degrading action of gastric fluid ($\text{pH} < 3$), and the drug molecules are thus protected from the acidic degradation. After gastric emptying, the CrDDS travels to the small intestine, and the intestinal fluid-soluble component in the coating membrane is dissolved away by the intestinal fluid

Fig. 22 Upper panel: Schematic illustration of Valrelease® tablet, a swelling-activated drug-delivery system, and the hydration-induced formation of colloid gel barrier. Lower panel: Comparison in the gastric residence profile between Valrelease with the conventional Valium capsule. (From Ref. 58.)

(pH > 7.5). This produces a microporous membrane of intestinal fluid-insoluble polymer to control the release of drug from the core tablet. The drug is thus delivered in a controlled manner in the intestine by a combination of drug dissolution in the core and diffusion through the pore channels. By adjusting the ratio of the intestinal fluid-soluble polymer to the intestinal fluid-insoluble polymer in the membrane, the rate of drug delivery can be regulated. Representative application of this type of CrDDS is in the oral controlled delivery of potassium chloride, which is highly irritating to gastric epithelium.

Ion-Activated Drug Delivery Systems

For controlling the delivery of an ionic or an ionizable drug, this type of CrDDS has been developed (2). Because the gastrointestinal fluid has regularly maintained a relatively constant level of ions, the delivery of drug by this type of CrDDS can be modulated, theoretically, at a constant rate.

Such a CrDDS is prepared by first complexing an ionizable drug with an ion-exchange resin, such as complexing a cationic drug with a resin containing SO_3^- group or an anionic drug with a resin containing $\text{N}(\text{CH}_3)_3^+$ group. The granules of the drug-resin complex are further treated with an impregnating agent, like polyethylene glycol 4000, for reducing the rate of swelling upon contact with an aqueous medium. They are then coated by an air-suspension coating technique with a water-insoluble but water-permeable polymeric membrane, such as ethylcellulose. This membrane serves as a rate-controlling barrier to modulate the release of drug from the CrDDS. In the GI tract, hydronium and chloride ions diffuse into the CrDDS and interact with the drug-resin complex to trigger the dissociation and release of ionic drug (Fig. 24).

This type of CrDDS is exemplified by the development of Pennkinetic® system (by Pennwalt Pharmaceuticals), which permits the formulation of oral liquid-type dosage forms with sustained release of a combination of

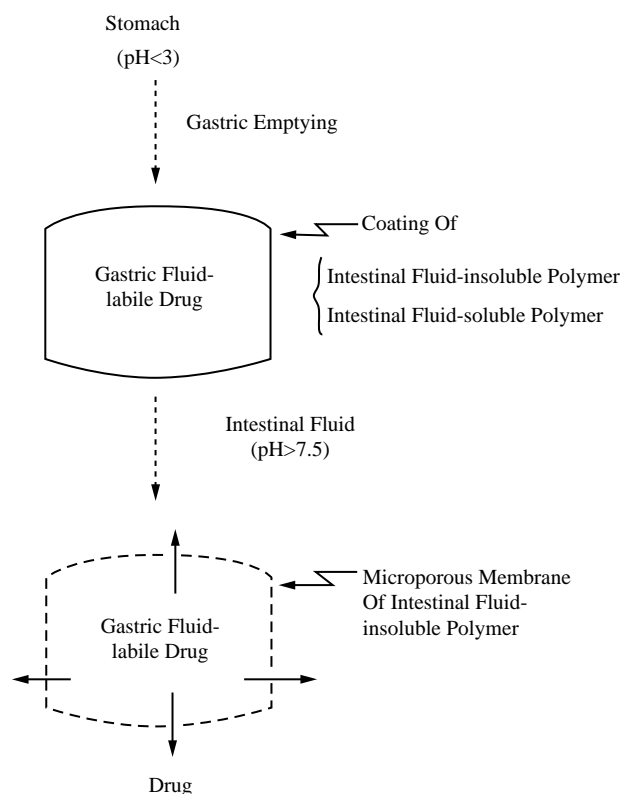

Fig. 23 Schematic illustration of a pH-activated drug-delivery system and the pH-dependent formation of microporous membrane in the intestinal tract.

hydrocodone and chlorpheniramine (Tussionex®) (14, 42–44).

Hydrolysis-Activated Drug Delivery Systems

This type of CrDDS depends on the hydrolysis process to activate the release of drug molecules. In this system, the drug reservoir is either encapsulated in microcapsules or homogeneously dispersed in microspheres or nanoparticles. It can also be fabricated as an implantable device. All these systems are prepared from a bioerodible or biodegradable polymer, such as polylactide, poly(lactide–glycolide) copolymer, poly(orthoester), or poly(anhydride). The release of a drug from the polymer matrix is activated by the hydrolysis-induced degradation of polymer chains, and the rate of drug delivery is controlled by polymer degradation rate (45). A typical example is the development of Lupron Depot®, an injectable microspheres for the subcutaneous controlled delivery of luprolide, a potent biosynthetic analog of gonadotropin-releasing hormone (GnRH) for the treatment of gonadotropin-dependent cancers, such as prostate carcinoma in men and endometriosis in the females, for up to 4 months. Another

example is the development of Zoladex® system, an implantable cylinder for the subcutaneous controlled delivery of goserelin, also a potent biosynthetic analog of GnRH for the treatment of patients with prostate cancer (Fig. 25) for up to 3 months (14).

Enzyme-Activated Drug Delivery Systems

In this type of CrDDS, the drug reservoir is either physically entrapped in microspheres or chemically bound to polymer chains fabricated from biopolymers, such as albumins or polypeptides. The release of drugs is made possible by the enzymatic hydrolysis of biopolymers by a specific enzyme in the target tissue (46–48). A typical example is the development of albumin microspheres, which release 5-fluorouracil, in a controlled manner, by protease-activated biodegradation.

FEEDBACK-REGULATED DRUG DELIVERY SYSTEMS

In this group of CrDDSs, the release of drug molecules is activated by a triggering agent, such as a biochemical

Fig. 24 Cross-sectional view of an ion-activated drug-delivery system, showing various structural components, and diagrammatic illustration of ion-activated drug release. (Adapted from Ref. 58.)

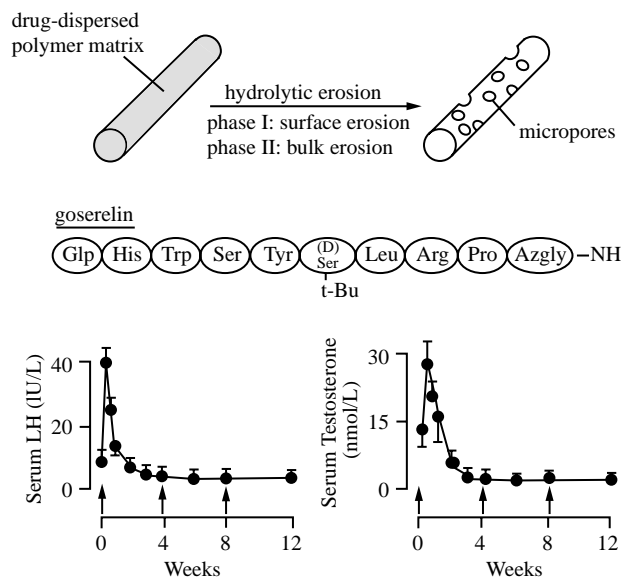

Fig. 25 Amino acid sequence of goserelin, a biosynthetic analog of gonadotropin-releasing hormone, and the effect of subcutaneous controlled release of goserelin from the biodegradable poly(lactide-glycolide) implant on the serum levels of luteinizing hormone and testosterone.

substance, in the body via some feedback mechanisms (Fig. 2). The rate of drug release is regulated by the concentration of a triggering agent detected by a sensor built into the CrDDS.

Bioerosion-Regulated Drug Delivery Systems

The feedback-regulated drug delivery concept has been applied to the development of a bioerosion-regulated CrDDS by Heller and Trescony (49). This CrDDS consists of a drug-dispersed bioerodible matrix fabricated from poly(vinyl methyl ether) half-ester, which was coated with a layer of immobilized urease (Fig. 26). In a solution with near neutral pH, the polymer only erodes very slowly. In the presence of urea, urease at the surface of the drug delivery system metabolizes urea to form ammonia. This causes the pH to increase and activates a rapid degradation of polymer matrix as well as the release of drug molecules.

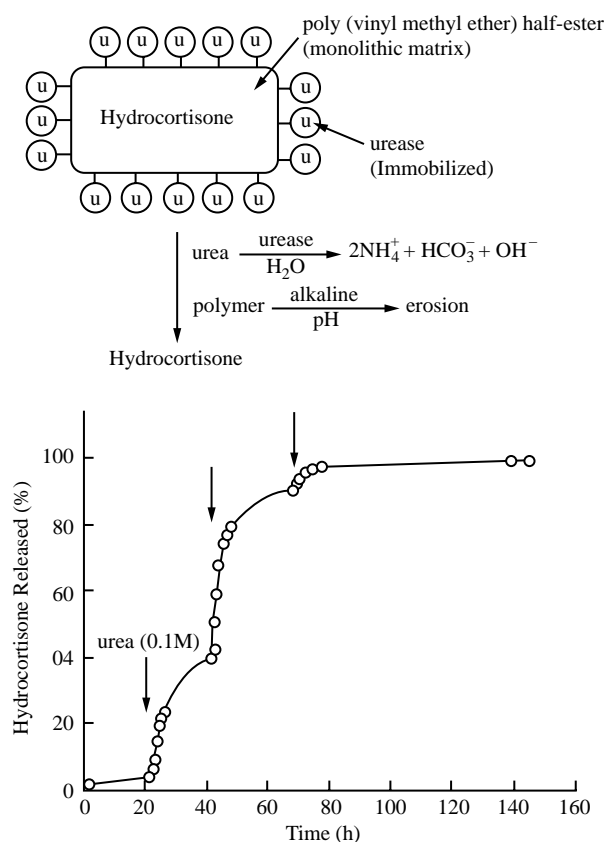

Fig. 26 Cross-sectional view of a bioerosion-regulated hydrocortisone delivery system, a feedback-regulated drug delivery system, showing the drug-dispersed monolithic bioerodible polymer matrix with surface-immobilized ureases. The mechanism of release and time course for the urea-activated release of hydrocortisone are also shown. (From Ref. 49.)

Bioresponsive Drug Delivery Systems

The feedback-regulated drug delivery concept has also been applied to the development of a bioresponsive CrDDS by Horbett et al. (50). In this CrDDS, the drug reservoir is contained in a device enclosed by a bioresponsive polymeric membrane whose permeability to drug molecules is controlled by the concentration of a biochemical agent in the tissue where the CrDDS is located.

A typical example of this bioresponsive CrDDS is the development of a glucose-triggered insulin delivery system, in which the insulin reservoir is encapsulated within a hydrogel membrane containing pendant NR_2 groups (Fig. 27). In an alkaline solution, the NR_2 groups exist at neutral state and the membrane is unswollen and thus impermeable to insulin. As glucose penetrates into the membrane, it is oxidized enzymatically by the glucose oxidase entrapped in the membrane to form gluconic acid. This process triggers the protonation of NR_2 groups to

Fig. 27 Cross-sectional view of a bioresponsive insulin delivery system, a feedback-regulated drug delivery system, showing the glucose oxidase-entrapped hydrogel membrane constructed from amine-containing hydrophilic polymer. The mechanism of insulin release, in response to the influx of glucose, is also illustrated. (From Ref. 50.)

form NR_2H^+ , and the hydrogel membrane becomes swollen and is thus permeable to insulin molecules (Fig. 27). The amount of insulin delivered is bioresponsive to the concentration of glucose penetrating into the CrDDS.

Self-Regulating Drug Delivery Systems

This type of feedback-regulated CrDDS depends on a reversible and competitive binding mechanism to activate and to regulate the release of drug. In this CrDDS, the drug reservoir is a drug complex encapsulated within a semipermeable polymeric membrane. The release of drug from the CrDDS is activated by the membrane permeation of a biochemical agent from the tissue where the CrDDS is located.

Kim et al. first applied the mechanism of reversible binding of sugar molecules with lectin into the design of self-regulating CrDDS (51). For this CrDDS, a biologically-active insulin derivative, in which insulin is coupled with a sugar (e.g., maltose), was first prepared and then conjugated with lectin to form an insulin–sugar–lectin complex. The complex is then encapsulated within a semipermeable membrane to produce CrDDS. As blood glucose diffuses into the CrDDS, it binds, competitively, with the binding sites in the lectin molecules and activates the release of the insulin–sugar derivatives from the binding sites. The released insulin–sugar derivatives diffuse out of the CrDDS, and the amount of insulin–sugar derivatives released depends on the concentration of glucose. Thus, a self-regulating drug delivery is achieved. However, a potential problem has remained to be resolved: that is, the release of insulin is nonlinear in response to the changes in glucose level (52).

Further development of the self-regulating insulin delivery system has utilized the complex of glycosylated insulin–concanavalin A, which is encapsulated inside a polymer membrane (53). As glucose penetrates into the system, it activates the release of glycosylated insulin from the complex for a controlled release from the system (Fig. 28). The amount of insulin released is thus self-regulated by the concentration of glucose that has penetrated into the insulin delivery system.

SITE-TARGETING DRUG DELIVERY SYSTEMS

Delivery of a drug to a target tissue that needs medication is known to be a complex process that consists of multiple steps of diffusion and partitioning. The CrDDSs outlined above generally address only the first step of this complex

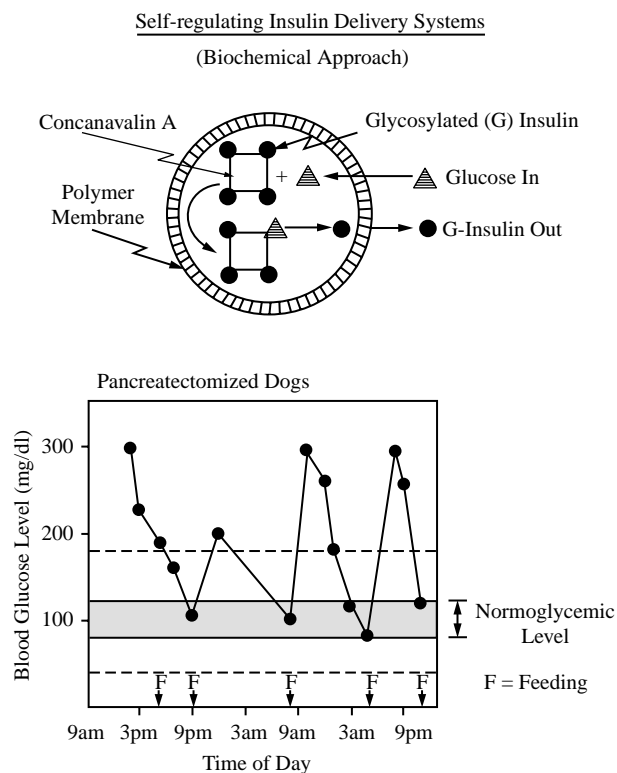

Fig. 28 Various components of a self-regulating insulin delivery system, a feedback-regulated drug delivery system, and its control of blood glucose level in the pancreatectomized dogs. (From Ref. 53.)

process. Essentially, these CrDDSs have been designed to control the rate of drug release from the delivery systems, but the path for the transport of drug molecules from the delivery system to the target tissue remains largely uncontrolled.

Ideally, the path of drug transport should also be under control. Then, the ultimate goal of optimal treatment with maximal safety can be achieved. This can be reasonably accomplished by the development of a CrDDS with a site-targeting specificity (Fig. 2). An ideal site-targeting CrDDS has been proposed by Ringsdorf (54). A model, which is shown in Fig. 29, is constructed from a nonimmunogenic and biodegradable polymer and acts as the backbone to contain three types of attachments: 1) a site-specific targeting moiety, which is capable of leading the drug delivery system to the vicinity of a target tissue (or cell); 2) a solubilizer, which enables the drug delivery system to be transported to and preferentially taken up by a target tissue; and 3) a drug moiety, which is covalently bonded to the backbone, through a spacer, and contains a linkage that is cleavable only by a specific enzyme(s) at the target tissue.

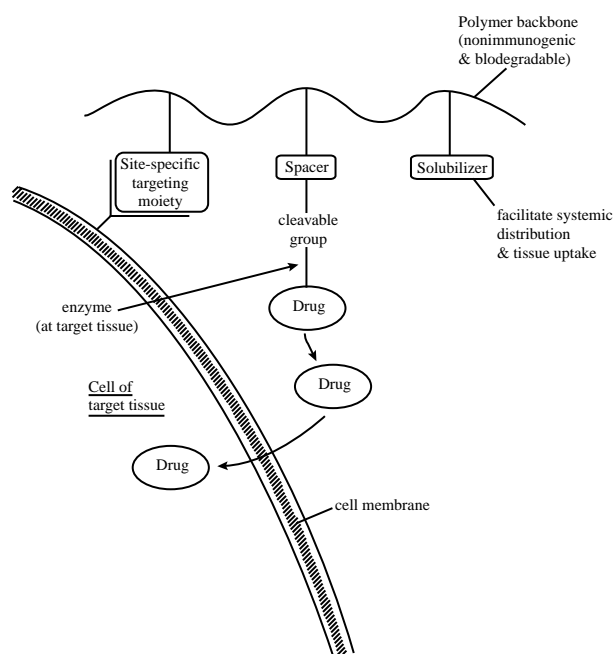

Fig. 29 An ideal site-targeting controlled-release drug delivery. (From Ref. 54.)

Unfortunately, this ideal site-targeting CrDDS is only in the conceptual stage. Its construction remains largely unresolved and is still a challenging task in the biomedical and pharmaceutical sciences.

SUMMARY

The controlled-release drug delivery systems outlined here have been steadily introduced into the biomedical community since the middle of the 1970s. There is a growing belief that many more of the conventional drug delivery systems we have been using for decades will be gradually replaced in the coming years by these CrDDSs.

DRUG DELIVERY—PULMONARY DELIVERY

Michael T. Newhouse

Inhale Therapeutic Systems, Inc., San Carlos, California, U.S.A.

OVERVIEW

New dispersible formulations and drug aerosol delivery devices for inhaleable peptides, proteins and various small molecules have, in the past decade, become of increasing interest for the treatment of systemic and respiratory diseases. These include, but also extend well beyond, the traditional and long available (although still underutilized) therapies for asthma and chronic obstructive pulmonary disease (COPD). Advances in the use of the lungs as portals for delivery of medication to the blood stream have greatly expanded the potential applications of pulmonary delivery. This advanced technology was initially applied to the systemic delivery of large molecules, such as insulin, interferon- β , or α_1 proteinase inhibitor. By facilitating the systemic delivery of large and small molecule drugs through inhalation deep into the lung, this advanced pulmonary technology provides a unique and innovative delivery alternative for therapies that must currently be administered by injection (i.v., i.m., s.c.) or by oral delivery that causes adverse effects or is poorly absorbed. Indeed, a major advantage of therapy via the lungs is the potentially improved therapeutic index, that is, the ratio of therapeutic benefit to adverse effects. This applies mainly to the therapy of pulmonary disease, but may also be applicable to systemic disease due to reduced first-pass metabolism that may be associated with hepatocellular injury. Pulmonary delivery also offers the potential for better and possibly more economical treatment or prophylaxis of respiratory and systemic diseases (e.g. viral vaccines).

ADVANTAGES OF INHALEABLES

Advanced technology for pulmonary delivery is expanding a category of drugs called “inhaleables,” defined as respiratory and systemic therapies administered simply by inhaling. Inhaleables offer several advantages over injectable, transdermal or oral methods of delivery that make them more appealing to both patients and physicians for treating a variety of diseases by means of currently available and future therapies.

First, inhaleables provide a noninvasive method of delivering drugs into the bloodstream for those molecules that currently can only be delivered by injection. These include peptides and proteins, such as insulin for diabetes or interferon beta for multiple sclerosis and most of the drugs developed in recent years by biotechnology companies. Inhale Therapeutic Systems, Inc. (San Carlos, California.) is pioneering advanced pulmonary drug delivery technology to provide a convenient and pain-free alternative to injection for systemic delivery of peptides and proteins. Feedback from patients in the clinical trials and extensive market research support the view that inhaleable drugs will be welcome alternatives to injections.

Second, inhaleables enable effective drug targeting to the lungs for relatively common respiratory tract diseases such as asthma, emphysema, bronchiectasis and chronic bronchitis. This direct delivery most often results in a better treatment outcome while potentially requiring less drug than if given systemically either orally or by injection.

Third, inhaleables provide for very rapid onset of action similar to the i.v. route and quicker than can be achieved with either oral delivery or subcutaneous injections. More rapid delivery could benefit treatments for pain, seizures, panic/anxiety attacks, hypertensive crises, anaphylaxis (severe allergies, food, insect bites), nausea, cardiovascular conditions (arrhythmia, strokes), and Parkinson's “lock-up”—indications where speed is important.

Fourth, inhaling instead of taking pills can help avoid gastrointestinal tract problems such as poor solubility, low bioavailability, gut irritability, unwanted metabolites, food effects and dosing variability.

MACROMOLECULES AND THEIR IMPORTANCE

Macromolecules are polymers composed of three or more amino acids, sugars, nucleotides, etc. While the large protein molecules are usually made by means of recombinant technologies, the smallest peptides are made primarily by chemical synthesis.

After nearly two decades of activity, innovations in biotechnology and recombinant gene techniques have led to an increase in the approved use of many macromolecule drugs. In recent years, at least 30 macromolecule medications have been approved for marketing in the United States alone, and more than 130 are now in human clinical trials, many for the treatment of chronic and subacute diseases that afflict a large percentage of people worldwide. This is particularly significant, as most of the diseases in question require multiple drug doses and, therefore, multiple injections over many years.

For many years, medical science has been looking for an alternative to injections for the delivery of macromolecule drugs. Due principally to their size, these molecules, mostly proteins and peptides, cannot naturally and efficiently pass through the skin or nasal membranes without the use of penetration enhancers, such as detergents or electrical impulses. If administered orally, they are digested or degraded before they reach the bloodstream. Therefore, oral, transdermal and nasal routes of delivery are inefficient for these molecules. In contrast, research has shown that many of those same molecules are absorbed naturally and quickly into the bloodstream if they are delivered to the deep lung through the use of inhaleables.

WHY IS PULMONARY DELIVERY THE BEST ROUTE?

At best, chronic injection is an unpleasant prospect with a host of hygiene issues and potential side effects. At worst, it can create a barrier to patient compliance with the particular drug regimen required to most effectively treat a given disease, since some patients choose irregular treatment or no treatment at all when faced with frequent injections.

While injection has served as the primary means of delivering macromolecules produced by biotechnology, many noninvasive routes have been explored as alternatives. Oral delivery remains the most common method of delivery for most small molecule drugs. However, oral delivery most often does not work for macromolecules because proteins are digested before they have an opportunity to reach the bloodstream. Commercially successful oral delivery of peptides and proteins has not been achievable with the exception of DDAVP (9 amino acids) and cyclosporin (11 amino acids), two digestion resistant small peptides.

The skin offers an even less naturally permeable boundary to macromolecules than the gastrointestinal tract. Thus, passive transdermal delivery of proteins and

peptides using “patch” technology has not succeeded. Peptides and proteins can be shot through the skin into the body using high-pressure “needle-less” injection devices. The devices, which inject proteins like insulin, have been available for years, however they have failed to impress doctors or patients due to the associated discomfort and the potential for “splash back” to transmit blood-borne diseases such as AIDS or hepatitis.

Nasal delivery is inefficient in terms of the amount of drug actually delivered to the body and to increase its efficiency, penetration enhancers must be added that may cause local irritation.

In contrast, research has shown that many molecules are absorbed through the deep lung into the bloodstream naturally with relatively high bioavailability and without the need for enhancers used by other noninvasive routes (1). With regard to the treatment of systemic disease, bioavailability is defined as the amount of drug that actually reaches the bloodstream by any method of delivery, compared to the mass of the agent with which the delivery “device” was charged.

The respiratory tract is accustomed to dealing with chronic exposure to a relatively large load of biological and nonbiological particulates. These are contained in the 20,000 L of air that must be inhaled daily to accomplish gas exchange. It is a tribute to the effectiveness of lung defense mechanisms that in healthy people, for most of their lives, the lungs are sterile below the larynx. According to the American Conference of Governmental Industrial Hygienists, a person can inhale approximately 30 mg/day of inert nuisance dusts into the lung day after day without effect (2), suggesting that the lung is a rather robust organ. Further, there is no evidence that inhaling autologous (self) proteins presents any immune response issues. The high bioavailability provided by the deep lung and the robustness of this organ make it a natural portal of entry for peptides, proteins and other small molecules that could be used to provide systemic therapy.

Riding on Air—Getting to the Deep Lung

The lung provides an enormous surface area through which molecules can be absorbed into the bloodstream. When a breath of air is inhaled, it travels down the trachea and the conducting airways to reach the alveolar epithelium. The conducting airways branch 12–23 times and their surface area measures approximately 0.8 m² in adults. The epithelium of the branching airways of the lungs are lined by a relatively thick, ciliated, pseudo-stratified columnar epithelial layer covered with low viscosity periciliary fluid. Floating above the periciliary

fluid are large “rafts” of thicker gel-like mucus which are propelled towards the pharynx by the rapidly beating cilia.

Once a drug aerosol has made its way through the conducting airways to deposit in the deep lung, the major barriers to entering the body are the 0.15 μm layer of type I alveolar cells that are covered by a very thin layer of epithelial lining fluid consisting mainly of surfactant and the relatively permeable endothelium of the alveolar capillaries. Alveolar cells have so called “tight” junctions that act as a relative barrier to the absorption of large molecules such as proteins and peptides and prevent the development of pulmonary edema.

THE ALVEOLAR EPITHELIUM

The alveolar epithelium measures approximately 100 m^2 in adults—approximately the size of a singles tennis court. It is made up of approximately 500,000,000 tiny airsacs, 300 μm in diameter, called alveoli. These are enveloped by an equally large capillary network and it is across this enormously large and extremely thin (0.1–0.2 μm) membrane that gas exchange and the transcytosis of large and small molecules occurs. The alveolar epithelium is composed of a thin, non-ciliated, nonmucus-covered cell layer consisting mainly of type I and type II fixed alveolar cells. A thin epithelial lining fluid, mainly surfactant, covers the type I and II alveolar epithelial cells.

Type I pneumocytes make up most of the epithelial surface. It is the large, thin, type I pneumocytes that are the primary site of pulmonary protein absorption. The type II pneumocytes, lying in niches between type I cells, are the main source of surfactants and also replace type I cells as they undergo apoptosis (programmed cell death) after about 120 days.

Beneath and extending between these cells are antigen evaluating and presenting dendritic cells. On the epithelial surface are motile phagocytes called macrophages, about 15 to each alveolus. These remove foreign biological and non-biological particles and assist in maintaining the sterility of the alveolar surface. Macrophages are the immune system's first line of defense against inhaled organisms. The key to preventing macrophages from engulfing inhaled drug particles is solubility. Ideally, drugs are rapidly dissolved in the epithelial lining fluid on the surface of the epithelium thus assisting their ingestion by macrophages. This process can be accelerated by means of small, drug-containing, lipid particles.

TRANSCYTOSIS

The body absorbs peptides and proteins into the bloodstream by a natural process known as transcytosis, which occurs deep in the lung. Transcytosis allows drug molecules to move across an impermeable cell membrane without creating holes in the cells and destroying the barrier (Fig. 1).

The process is performed by trillions of tiny membrane bubbles, or transcytotic vesicles, which form from invaginations of the cell membrane on one side of the cell and fuse back into the membrane on the other side of the cell. The result is that small volumes of alveolar fluid, containing dissolved proteins, are rapidly carried by a “bucket brigade” from one side of the alveolar cell to the other.

Small molecules and peptides are also thought to be absorbed through the lung surface by an analogous process called paracellular transport. This is achieved through the tight junctions which connect cells to each other. However, in contrast to transcytosis that is rapid and efficient, paracellular transport is slow and inefficient.

Many dissolved proteins that have been transported through the alveolar cells are rapidly reabsorbed into the blood through the capillary endothelial cells (also by

Fig. 1 Natural absorptive mechanism. The body absorbs peptides and proteins into the bloodstream by a natural process known as transcytosis which occurs deep in the lung. Transcytosis is the process by which large molecules move across an impermeable cell membrane without creating holes in the cells and destroying the barrier. It is performed by tiny membrane bubbles, or transcytotic vesicles, which form invaginations of the cell membrane on one side of the cell and dissolve back into the membrane on the other side of the cell. The result is that small volumes of alveolar fluid, including dissolved proteins, are carried by a “bucket brigade” from one side of a cell to the other.

transcytosis). In the case of some large proteins, they are more slowly drained across the interstitial space by means of the pulmonary lymphatics, which also empty into the bloodstream via the thoracic duct and superior vena cava.

The purpose of transcytosis in lung biology is not clearly understood. It is thought to be a natural mechanism for controlling the level of airway fluid and for moving endogenous proteins back and forth across the epithelium during normal physiological “housekeeping.” Both transcytosis and paracellular transport are sophisticated cell processes mediated by complex cell machinery.

The result of these two processes is a noninvasive means of delivering proteins and peptides to the bloodstream with relatively high bioavailability and without the use of penetration enhancers (3).

Because the molecules are delivered rapidly into the bloodstream, there is a much more rapid onset of action than with any other non-i.v. delivery method. This can be particularly useful in indications where speed is important such as pain control, relief of muscle spasm, panic/anxiety attacks, hypertensive crises, cardiac arrhythmias, anaphylaxis (severe allergies to food and insect bites), nausea, cardiovascular conditions (arrhythmia, strokes), Parkinson’s “lock-up,” and epileptic seizures.

Characteristics of Lung Absorption

Large, highly vascularized area available for transcytosis

Conducting airways $\sim 0.8 \text{ m}^2$

Alveoli $\sim 80 \text{ m}^2$

Alveoli highly permeable to many biologics; most small molecules and many macromolecules capable of absorption throughout the respiratory tract

Relatively rapid, first-order absorption

Much less first-pass metabolism and degradation in the gastrointestinal tract and liver

Cytochrome P450 enzyme concentration in human lungs $< 0.7\%$ that of liver

Only 1A1 and 4B1 P450 isozymes reported in the human lung

CLINICAL APPLICATIONS OF PULMONARY DELIVERY

Pulmonary drug delivery in our post-genomics era has opened the door to noninvasive administration of a wide variety of macromolecules. Since drug delivery by the pulmonary route is now practical, drug companies can reconsider the development of new macromolecules and small molecules whose markets are limited as an

injectable or when given by mouth. Furthermore, rather than spending years to develop an oral version (or abandon a project altogether) especially for chronic or subchronic therapies, pharmaceutical companies can save years of development time by using pulmonary delivery for their macromolecule drugs. Pulmonary delivery could also replace some oral drugs due to the much faster onset of action with improved absorption and avoidance of first pass losses with delivery through the GI tract.

Nearly every biotherapeutic product involving chronic or longterm use would benefit from noninvasive delivery, which could provide pharmaceutical companies with a competitive advantage, expand the market for products and/or enable new indications to be considered. Further, proprietary new inhalation delivery systems can extend the patent life of a drug, increase patient compliance and possibly reduce healthcare costs.

Because of the advances in biotechnology that have resulted not only in new macromolecules but also in new devices to deliver them via the lungs, patients and physicians will soon be able to use this route to treat diseases such as diabetes, hepatitis, osteoporosis, multiple sclerosis, genetic emphysema, cystic fibrosis, and other pulmonary infections among others.

Pulmonary delivery could also be used for delivery of vaccines. In the United States alone, children endure as many as 14 vaccine injections by age 16 and that number is climbing as new research makes more vaccines available. The cost of a single injection can quadruple if the costs of equipment and personnel are included. Furthermore, fear of needles reduces compliance, thus the potential for an increased market share in this area. Inhaled vaccines may be used to prevent influenza, pneumonia, tuberculosis, measles, cytomegalovirus, asthma, and mucosal-entry diseases such as sexually transmitted diseases including HIV.

PULMONARY DISEASE AND PULMONARY DELIVERY

Pulmonary drug targeting has long been used to treat lung disease, particularly asthma and COPD, non-CF and CF bronchiectasis, bronchiolitis and recently influenza. Potentially, other pulmonary diseases such as parenchymal fibrosis, acute bronchitis, pneumonia and even carcinoma of the lung in situ might be treated by inhalation. Secondary lung malignancies have been treated by inhalation of IL2 and GM-CSF with some benefit.

With regard to pulmonary infections, much higher concentrations of antibiotics can be achieved in the lungs

by inhalation, which should accomplish greater and more rapid bacterial killing with less likelihood of developing bacterial resistance. Furthermore, topical delivery achieves reduced systemic side effects for equivalent therapeutic benefit.

CHALLENGES AND SOLUTIONS IN PULMONARY DELIVERY

In the mid-1950s the first pressurized metered dose inhaler (MDI) was developed for the administration of bronchodilator drugs locally to the lung. It was a major advance for the treatment of asthma since it made aerosol medications readily available in an inexpensive small multidose device.

The world aerosol market has grown due to the increased incidence of asthma and chronic obstructive pulmonary disease (COPD) as well as due to an increased number of patients receiving aerosol medications as the drug formulation-device combination of choice. Until recently, companies developed pulmonary drug delivery systems primarily to dispense drugs to the airways of the lung for local lung applications. Application systems such as pressurized metered dose inhalers (pMDIs), breath activated dry powdered inhalers (DPIs), liquid jet and ultrasonic nebulizers have proved useful in the management of airway inflammation and bronchoconstriction.

For the systemic delivery of most drugs, however, currently marketed aerosol delivery systems are inadequate due to the following:

1. *Low System Efficiency:* To be commercially feasible for the administration of costly proteins and peptides, the overall efficiency of presently available systems has remained generally too low. Correct aerosol particle size is very important for optimum deep lung delivery. Studies have established that these particles should range from one to three microns in aerodynamic diameter for optimum lung deposition efficiency. If the particles are too large, they impact in the oropharynx and larynx. If they are too small, they will be exhaled. Most existing MDI systems can only deliver a small fraction (about 10–20%) of the dispensed drug in the correct particle size for deep lung deposition (4–6) although, recently developed 1 μm solution aerosols from corticosteroid pMDIs have achieved lung deposition efficiencies of 60% or more.
2. *Low Drug Mass per Puff:* With most existing systems, the total amount of drug per puff delivered to the lower respiratory tract is too low—less than 1000 mcg (6)—to enable practical delivery of many macromolecules which require milligram doses. Device payload

versatility is an important feature with the new macromolecule drugs since they come in a wide variety of potencies—from a few micrograms per dose to tens of milligrams. Traditional inhalation systems have primarily been designed to deliver some of the most potent drugs in use today, namely the inhaled bronchodilators and corticosteroids used for treating asthma. Both of these classes of medication are bioactive in the lung at 5–50 $\mu\text{g}/\text{dose}$. In contrast, many peptide and protein drugs require deep lung doses in the 2–20 mg/dose range (1).

3. *Poor Formulation Stability for Macromolecules:* existing aerosol systems are not designed to protect the formulations of delicate macromolecules. Most traditional small molecule asthma drugs are crystalline and, in the case of corticosteroids, relatively moisture resistant in the dry state. They are also rather stable in liquids as compared to most macromolecules, which are unstable in the liquid state, amorphous, and highly moisture sensitive in the dry state. There are exceptions, including Genentech's Pulmozyme, the first FDA approved aerosol protein, a 33 kDa digestive enzyme (DNAse) used to break up the thick, grossly infected, mucus in cystic fibrosis. It is available as a stable liquid formulation for nebulization. Other proteins such as growth hormone, G-CSF and Interferons aggregate and are partially denatured by nebulization (7).
4. *Poor Dosing Reproducibility:* for a variety of reasons, the dosing reproducibility of many existing systems is too variable for systemic delivery of most macromolecule drugs (6, 8). Physicians and patients alike have tolerated the highly variable dosing of inhaled asthma medications for years because the drugs have a wide therapeutic window and optimizing the drug dose is usually a matter of trial and error. In the case of the bronchodilators, the rapid improvement characterized by easier breathing has enabled patients to know whether or not they have used the proper inhalation technique and dose. So far, no macromolecule drug appears to possess such rapid biofeedback.

Potential solutions to these challenges to ensure effective inhalation drug treatment include active dry powder delivery systems, active liquid blister technology, and hydrofluorocarbon (HFC) propellant nebulization systems.

Dry Powder Inhalation (DPI) Systems

Dry powder aerosols are frequently highly soluble and quickly dissolve in the fluid layer lining the surface of the deep lung before passing through the thin cytoplasm of the

type I alveolar cells the interstitial “space” and capillary endothelium. The main advantages of dry powder systems include product and formulation stability (even at room temperature or above), the potential for delivering a low or high mass of drug per puff, low susceptibility to microbial growth, and applicability to both soluble and insoluble drugs.

Current challenges facing the development of these systems for macromolecules include moisture control, efficient powder manufacturing, reproducible powder filling, unit dose packaging and development of efficient reliable aerosol dispersion and delivery devices.

One of the challenges is that the fine powder particles tend to stick to each other. These clumps can be difficult to break apart into breathable particles for slow inhalation by the patient. Breath-powered powder inhalers for asthmatics attempt to apply the forces generated by a rapid forceful inspiration to break apart the powder clumps. But vigorous rapid inhalation does not efficiently deaggregate and target the very fine powder clumps to the deep lung. This is mainly because particle inertia causes impaction of most of the medication in the oropharynx.

One solution to the clumping problem for macromolecule drug delivery is to use a device with sufficient power to force the deaggregation of even fairly adhesive powders. One company working on this issue, Inhale Therapeutic Systems, of San Carlos, California, has designed a device that uses sonic velocity compressed air (1.5 mL) to aerosolize the powder (Fig. 2). Systemic Delivery. These de-agglomerated particles form a standing cloud in an aerosol holding chamber. The patient then inhales the stationary cloud with one slow, rate controlled deep breath, eliminating the need for patient coordination between the generation of the aerosol powder and inhalation. Furthermore, the slow deep breath encourages efficient alveolar delivery of the drug.

The keys to efficient aerosol targeting to the deep lung are:

1. Formulation of readily dispersible powders by particle engineering
2. A device that is small, inexpensive and user-friendly to generate the drug aerosol, and
3. Inhalation at a low inspiratory flow rate (below 20 L/min) to minimize upper airway and large airway deposition.

Liquid Systems

Liquid systems provide ease of filling and availability (in some cases) of preexisting injectable formulations for macromolecules. These systems, however, also pose

Fig. 2 Advanced inhaler technology for pulmonary systemic delivery. Shown here: a collapsed and extended advanced inhaler used for systemic delivery. A patient would use this device and powdered medicine instead of receiving an injection or taking a pill. The device slides open and closed like a telescope for compact carrying, making it portable for patients who must self-administer drugs regularly. A patient would open the device, insert a blister of powdered medicine and then pump the handle which compresses a small amount of air inside the device. By pushing a button, the patient causes the compressed air to be released at extremely high velocity, breaking apart the powder from the blister and sending it into the 200-mL chamber where it is captured as a stationary cloud. When patients inhale this fine powder formulation of the drug as an aerosolized cloud, they receive the medicine first and then a volume of air that helps push the drug deep into the lung, where it is absorbed into the blood.

hurdles for their use with protein and peptide drug delivery. They currently offer lower drug payload per puff than dry systems (because more than 95% of the mass is

water), difficulty in formulation stabilization (particularly for insoluble drugs), and greater susceptibility to microbial growth within a device. Current challenges facing the development of liquid systems for macromolecules are formulation stability, unit dose packaging, high payload delivery and development of efficient reliable devices.

One of the oldest medical aerosol delivery systems is the air jet nebulizer, which forms a fine mist of liquid droplets from a drug solution that a patient breathes over a period of 10–30 min/dose. The cumbersome electric powered jet nebulizer is often used as a fallback delivery system for asthmatics who do not appear to be getting relief from the small portable MDIs and DPIs. Nebulizers are very hard on macromolecules and cause aggregation in the device before some macromolecules can be inhaled (7).

Some companies are focusing on the development of a new generation of liquid systems that are portable, more efficient, more gentle on the macromolecule and that can deliver the medicine in far fewer puffs than the old fashioned nebulizer. Two companies who are developing advanced pulmonary delivery liquid systems are Aradigm Corporation, Hayward, CA, and AeroGen, Inc., Sunnyvale, CA.

Propellant Systems

The best example of propellant-powered systems is the well-known little canister inhalers (pressurized metered dose inhalers or pMDIs) used by asthmatics since the 1950s. The original, ozone-depleting chlorofluorocarbon (CFC) propellants are being replaced by the more environmentally friendly hydrofluorocarbons (HFCs). HFC propellant systems give patients the convenience of small, inexpensive multidose devices that can be filled easily. However, they appear at this time not to be amenable to stable formulating of macromolecular therapeutic applications. Current designs deliver low payloads per puff, have low lung delivery efficiency, poor stability for water-soluble macromolecules and moderately high dosing variability (6).

OTHER ISSUES REGARDING PULMONARY DELIVERY

Notwithstanding the scientific advances in this field, many still have concerns about acceptable bioavailability and reproducibility with pulmonary delivery while others harbor some fears about the safety of deep lung inhalation of macromolecules.

Dose reproducibility: Several human studies comparing aerosol insulin administration to subcutaneously administered insulin showed that the variability in glucose response from a liquid nebulizer that utilized the standing cloud concept was equivalent or better than that seen with insulin injection (9). Inhale Therapeutics Systems, Inc. has adopted this standing cloud concept for its dry powder inhaler to achieve reproducibility of delivery of macromolecules to the systemic circulation that is equivalent to subcutaneous injections.

Safety: A growing body of data indicates that inhaling proteins can be safe, whether the patient has healthy lungs or a pulmonary disease (see Table 1). With relatively stable lung diseases, unless the damage or deterioration of the lung parenchyma is very severe—that is, if the patient has lost over 60% of lung function—most researchers do not expect systemic variability from pulmonary delivery to differ from that seen with injections. With typical upper respiratory diseases such as colds and flu, lung function is thought to remain within 70–100% of normal. Even with a cold or flu where inspiratory capacity can fall up to 30% below normal, a deep breath that is 70% of a normal deep inspiration can deliver the aerosol drug into the lungs if the standing cloud technique is used to provide an aerosol bolus at the very beginning of a slow deep breath.

Despite considerable clinical experience with aerosolized macromolecules, there have been no serious safety issues to date, nor have there been significant problems with throat irritation or cough. So far, the proteins and peptides under development for human applications have

Table 1 Aerosol safety of peptides and proteins

Molecule	Study ^a
Insulin	89 patients 24 months
DNase	Approximately 10,000 patients Almost four years
Heparin	544 patients 1 day to 1.3 years
Interferon- α	16 patients Up to 67 weeks
Leuprolide acetate	Hundreds of patients 6 months
α_1 -Antitrypsin	12 patients 1 day; 1–7 days
Antibiotics	Hundreds of patients Up to 2 years
Interferon- γ	5 patients 12 days

^aNone of these studies had any adverse effect on lung.
(From Refs. 10–17.)

been virtually tasteless and the incidence of cough, with properly formulated drugs, has been very low. However, large particle sizes (more than 5 μm) can cause cough regardless of chemical composition, so it is important that particle sizes be kept in the so-called fine particle range (i.e., less than 5 μm).

Given the advances in pulmonary delivery technology, the issues for drug companies and patients concerning pulmonary delivery revolve around economic evaluations, approvals, administration and managed health care. As these issues are resolved, pulmonary delivery will doubtless become regarded as one of the leading drug delivery alternatives.

DRUG DELIVERY—PARENTERAL ROUTE

Michael J. Akers

Cook Pharmaceutical Solutions, Bloomington, Indiana, U.S.A.

INTRODUCTION

The *United States Pharmacopoeia* 24 (1) defines a small-volume injectable (SVI) as “an injection that is packaged in containers labeled as containing 100 ml or less.” Therefore, all sterile products packaged in vials, ampuls, syringes, cartridges, bottles, or any other container that is 100 ml or less fall under this classification. Ophthalmic products packaged in squeezable plastic containers, although topically applied to the eye rather than administered by injection, also fall under the classification of small-volume injections as long as the container size is 100 ml or less. (See the article Ocular Drug Formulation and Delivery in this encyclopedia). Large-volume injectables (LVI) have to be terminally sterilized, whereas SVIs can be sterilized terminally or by aseptic filtration and processing. In fact, 80% or greater of all SVIs commercially available are prepared by aseptic processing. LVIs usually involve intravenous infusion, dialysis, or irrigation fluids containing electrolytes, sugar, amino acids, blood, blood products, and fatty lipid emulsions (2). LVIs must be administered by intravenous administration. Small-volume injections may be injected by intravenous, subcutaneous, or intramuscular routes (primary routes of parenteral administration) or by various secondary routes such as intra-abdominal, intra-arterial, intra-articular, intracardiac, intracisternal, intradermal, intraocular, intrapleural, intrathecal, intrauterine, or intraventricular injections.

SVI formulations are relatively simple, composed of the active ingredient, a solvent system (preferably aqueous), a minimal number of excipients present for reasons described later in this chapter, and the appropriate container and closure packaging system. If the active ingredient is unstable in solution or suspension, the product can be a dry powder, processed either by lyophilization or by sterile crystallization.

This chapter introduces the basic aspects of small-volume injectable products—their use, types and primary characteristics of dosage forms, formulation ingredients, and packaging systems. Additional information is available in a variety of reference texts and book chapters (2–7). Only conventional SVI formulations are

addressed in this chapter. Advanced, long-acting (depot) formulations are not covered.

PRIMARY USES OF SMALL-VOLUME INJECTABLES

Small-volume injectables can be therapeutic injections, ophthalmics, diagnostics, radiopharmaceuticals, or allergenic extracts. The active ingredients can be intended for human or animal therapy and can be small molecules, proteins and other large molecules, biologics, vaccines, monoclonal antibodies, antisense oligonucleotides, and, in the future, genes.

Therapeutic Injections

Injections include a wide variety of therapeutic agents, e.g., for the treatment of cancer, infection, cardiovascular disease, arthritis and other inflammatory diseases, diabetes, hormonal deficiencies, central nervous system problems, and many other disease states. There are more than 400 injection products listed in the USP and, because of the huge number of biotechnology molecules in clinical study, this number will continue to grow rapidly over the next several years. Injections are primarily solutions containing the active ingredient and other substances. Product solutions are available either as “ready-to-use” (e.g., amobarbital sodium for injection) or solutions after reconstituting lyophilized (e.g., Gemzar[®]) or crystallized dry powder products (including many injectable cephalosporins). Some solutions may contain only the drug, e.g., vancomycin hydrochloride solution after reconstitution. Some products are suspensions in which the drug is suspended in a suitable medium, again either commercially available as a ready-to-use suspension (e.g., Humulin[®] N) or reconstituted as a suspension rather than as a solution (e.g., amoxicillin for injectable suspension). Injections can also be commercially available as concentrated liquids (e.g., potassium chloride for injection concentrate) that must be diluted before administration. Injectable products are either single dose or multiple dose. Multiple-dose

injections must contain an antimicrobial preservative agent(s), and the volume of injection should not exceed 30 ml (8).

Ophthalmic Products (9)

Ophthalmic drug products include drugs in solution, suspension, gel, or ointment, administered topically to the corneal surface of the eye. Ophthalmic products also include irrigating solutions in LVI sizes. There are many different types of ophthalmic drug products to treat glaucoma, infection, inflammation, and other diseases of the eye. Ophthalmic products must be sterile, but because they are topically applied, they are not required to be pyrogen-free. Ophthalmic solutions and suspensions are usually packaged in squeezeable low-density polyethylene containers for easy administration. Ophthalmic ointments are also sterile and must be free from metallic particles; they are packaged in ointment tubes. Because ophthalmic products are multiple-dose products, they must contain antimicrobial preservative agents. Because of plastic packaging, most ophthalmic products are aseptically processed.

Diagnostic Agents Including Diagnostic Radiopharmaceuticals (10)

There are many SVI diagnostic agents available including solutions containing contrast media and solutions containing radioactive iodine, chromium, technetium, iron, and other radioactive elements. These products are used primarily to evaluate organ functions. Contrast media solutions are stable in solution and, in fact, can be terminally sterilized. Most radioactive agents are produced to be used within hours of preparation because of the very short half-lives of the radioactive element. As with other sterile dosage forms, diagnostic agent products are to be sterile, pyrogen-free, and particulate-free.

Allergenic Extracts (11)

Allergenic extracts are sterile concentrates (solutions or suspensions) of the substances (allergens) responsible for unusual sensitivities in humans. These products can be used for therapeutic or diagnostic purposes. Extracts are aqueous (0.9% sodium chloride used as the diluent) or glycerinated (50% glycerin as the diluent). Most preparations are buffered at pH 8 and contain phenol ($\leq 0.4\%$) as an antimicrobial preservative. They are sterilized by aseptic filtration.

FORMULATIONS

Small-volume injectables are usually considered small-volume solutions in vials or ampuls but are available in a variety of dosage forms and packaging systems.

Liquids

Small-volume injectable liquids are primarily aqueous solutions. However, because many important therapeutic agents are poorly soluble or totally insoluble in water, oily solvents and water-miscible cosolvents are used to produce ready-to-use solutions.

Aqueous solutions

Aqueous ready-to-use SVIs contain the active ingredient, additional substances, if necessary, and water as the solvent. Water-for-injection (WFI), USP, is the solvent of choice for aqueous SVIs. WFI is prepared by distillation or reverse osmosis techniques. Of all the USP types of water (Table 1), WFI is the purest form of water available for sterile products. An essential requirement of WFI is its freedom from pyrogenic contamination. WFI and other USP types of water are now required to pass a certain specification for endotoxin concentration (see Table 1). Endotoxins are pyrogens with pyrogens being metabolic byproducts of microbial growth and death that cannot be destroyed by autoclaving or by sterilizing membrane filters. Aqueous SVI solutions are prepared either by filling the product into containers, sealing, and terminally sterilizing the finished product or, for drugs that cannot physically or chemically withstand high temperatures or radiation doses required for terminal sterilization, the drug product is sterile-filtered and aseptically filled into the final container and the container sealed by aseptic processing.

Nonaqueous solutions

Several SVIs are marketed as oily solutions (Table 2). The oil must be of vegetable origin (sesame, olive, or cottonseed oils are most commonly used) because of safety, purity, and biocompatibility considerations. Oils for injection must meet USP requirements (12):

1. Solid paraffin test (measurement of oil clarity);
2. Saponification value between 185 and 200;
3. Iodine value between 79 and 128; and
4. Test for unsaponifiable matter and free fatty acids.

Oily solutions are prepared by separately sterilizing the solvent, usually using dry heat, and the drug (dry heat or a gas such as ethylene oxide), then combining the solvent and drug aseptically. Terminal sterilization cannot be used for

Table 1 Types of water described in the *United States Pharmacopeia*

Type	Preparation	Pryogen-Free	Comments
Purified water USP	Distillation or ion exchange	No	Pharmaceutical solvent
Water for injection USP (WFI)	Distillation or reverse osmosis	Yes ^a	Not sterile. Must be used within 24 h or stored below 5°C or ≥80°C; used for manuf. of parenteral products to be sterilized
Sterile water for injection USP	Distillation or reverse osmosis	Yes ^a	Same as WFI; single-dose containers; also used to reconstitute sterile solids and dilute sterile solutions
Bacteriostatic water for injection USP	Distillation or reverse osmosis	Yes ^a	Multiple and single dose
Sterile water for irrigation USP	Distillation or reverse osmosis	Yes ^a	1 L or larger, wide mouth, does not meet particulate matter requirements for LVI; labeled “For Irrigation Only”

^a ≤0.25 endotoxin units per mL.

oily solutions because of the lack of moisture in the product necessary to generate saturated steam under pressure required to destroy microbial life. Practical development experiences with oily injection formulations have been reported by Sims and Worthington (13) and Radd et al. (14).

Cosolvent

A fairly large number of SVIs contain cosolvent systems; a partial listing of commercial products is given in Table 3.

Table 2 Small-volume parenteral products containing oil(s) as the solvent system

Product, USP XXII	Oil
Ampicillin (suspension)	Vegetable
Desoxycorticosterone acetate	Sesame
Diethylstilbestrol	Sesame, cottonseed
Dimercaprol (suspension)	Peanut
Epinephrine (suspension)	Sesame
Estradiol benzoate	Sesame
Estradiol cypionate	Cottonseed
Estradiol valerate	Sesame
Estrone	Sesame
Ethiodized iodine	Poppyseed
Fluphenazine enanthate	Sesame
Hydroxyprogesterone caproate	Sesame
Menadione	Sesame
Nandrolone decanoate	Sesame
Penicillin G procaine (suspension)	Vegetable
Propylidone (suspension)	Peanut
Testosterone cypionate	Cottonseed
Testosterone enanthate	Sesame
Testosterone propionate	Sesame

(From Ref. 4.)

Cosolvents are used to increase the solubility of the poorly soluble drug in water. Cosolvents also tend to minimize or even prevent drug chemical degradation by hydrolysis, obviously because of the reduction in the percentage of water in the system. Water-miscible cosolvents operate on the principle of lowering the dielectric constant property of water, thereby increasing the aqueous solubility of poorly water-soluble drugs. Depending on drug stability, products containing cosolvents can be sterilized terminally using saturated steam under pressure. Otherwise, such products are prepared by aseptic processing. A primary concern in using cosolvents in injectable formulations is their potential to cause lysis of red blood cells when administered intravenously (15). Therefore, any addition of a cosolvent to a formulation intended for parenteral administration must be studied for its safety and potential toxicological effects.

Solids

SVIs are available as sterile dry solids that must be reconstituted with a diluent, usually sterile water for injection, USP, before being administered as a solution or suspension. Sterile dry SVIs are prepared using two primary methods.

Freeze-drying

Most commercial sterile dry powders are manufactured by freeze-drying, also called lyophilization. In this process, under strict aseptic conditions, the product is aseptically filtered and filled as a solution. Special slotted rubber closures are inserted partially onto the vials, which are then transferred to a freeze dryer. Freeze-drying involves three primary operations:

Table 3 Small-volume parenteral products containing cosolvents

Trade Name	Manufacturer	Cosolvent composition
Dramamine	Searle	50% propylene glycol
Apresoline	Ciba	10% propylene glycol
MVI	US Vitamins	30% propylene glycol
Nembutal	Abbott	40% propylene glycol, 10% ethanol
Luminal	Winthrop	67.8% propylene glycol
Dilantin	Parke-Davis	40% propylene glycol, 10% ethanol
DHE 45	Sandoz	15% glycerin, 6.1% ethanol
Cedilanid	Sandoz	15% glycerin, 9.8% ethanol
Robaxim	Robbins	50% polyethylene glycol
Serpasil	Ciba	50% polyethylene glycol, 10% dimethylamine
Ativan	Wyeth	20% polyethylene glycol, 80% propylene glycol
Librium	Roche	20% propylene glycol
Valium	Roche	40% propylene glycol, 10% ethanol
Lanoxin	Burroughs Wellcome	40% propylene glycol, 10% ethanol

From Yalkowsky, S.; Roseman, T., *Techniques of Solubilization of Drugs*; Marcel Dekker, Inc.: New York, 1981; 91.

1. Freezing the product below its eutectic temperature (for crystalline materials) or below its glass transition temperature (for amorphous materials);
2. Primary drying in which the frozen solvent is sublimed, a phase transition from a solid directly to a gas; and
3. Secondary drying in which solute bound water is removed to an acceptable product moisture level for long-term stability.

At the completion of the freeze-dry cycle, the partially inserted rubber closures are fully seated in the vials. The finished product contains a white or off-white sterile dry powder.
